The Pathophysiology and Genetics of Type 2 Diabetes Mellitus

Steven E. Kahn

Daniel Porte, Jr.

Both fasting hyperglycemia and excessive increases in glucose concentration following oral glucose loading are criteria for the diagnosis of type 2 diabetes mellitus (T2DM). In both the post-absorptive and fed states, three important defects have been demonstrated in subjects with T2DM: (1) impaired basal and stimulated insulin secretion, (2) an increased rate of endogenous hepatic glucose release, and (3) inefficient peripheral tissue glucose use. In this chapter we will review the closed feedback loop comprising the pancreatic islet, liver, and peripheral tissues, which together are responsible for the regulation of plasma glucose. Then we will describe the nature of the three major defects observed in T2DM and how they interact in the pathophysiology of hyperglycemia. We will use this same feedback loop to provide a perspective of how the different therapeutic interventions act to alter the steady-state glucose level. Finally, we will discuss studies of the genetic basis for hyperglycemic syndromes including type 2 diabetes, maturity-onset diabetes of the young (MODY), and other rare genetic forms of T2DM.

NORMAL PHYSIOLOGY OF GLUCOSE REGULATION

The maintenance of a stable fasting plasma glucose level is dependent on a closed feedback loop relationship between the circulating glucose level and the pancreatic islet hormones (Fig. 21-1). After an overnight fast, glucose is produced largely in the liver by glycogen breakdown and gluconeogenesis, and the rate of production is dependent on the availability of hepatic glycogen and gluconeogenic precursors. About 80% of this glucose released by the liver is metabolized independent of insulin by the brain and other insulin-insensitive tissues, such as the gut and red blood cells. Insulin-sensitive tissues, such as muscle and fat, use only small quantities. A number of neural and hormonal influences regulate hepatic glucose production, and in the presence of adequate amounts of insulin, the glucose level itself can regulate hepatic glucose release.^{1,2} Short-term hormonal regulators of physiologic importance include insulin, glucagon, and the catecholamines; a more long-term influence on hepatic glucose production is provided by growth hormone, thyroid hormone, and glucocorticoids.

The liver is exquisitely sensitive to changes in insulin and glucagon levels, which, due to the fact that these hormones drain

directly into the liver, are ideally suited to regulate moment-to-moment changes in hepatic glucose output. A reduction in insulin concentration removes the inhibitory effect of insulin on the liver and permits a slow rise in hepatic glucose production and the development of hyperglycemia.³ On the other hand, a decrease in the glucagon level reduces glucose production by the liver and is associated with a concomitant fall in plasma glucose level.^{4,5} Restoration of the original plasma glucose level will occur if the feedback loop is intact due to the effect of the glucose level to in turn regulate pancreatic insulin and glucagon secretion. In situations in which peripheral insulin sensitivity changes, this will also be reflected by a change in plasma glucose level. For example, if peripheral glucose use decreases, a rise in the fasting plasma glucose level will occur, to which the pancreatic islet will appropriately modify its secretion by reducing glucagon output by the α cell and increasing insulin secretion by the β cell. These secretory changes will reduce the rate of hepatic glucose output so that the glucose level will tend to be restored to near normal. In instances in which peripheral glucose use rises, the opposite will occur, so that hepatic glucose production will increase and glucose level will once again return toward normal. It is important to realize that complete islet adaptation cannot occur; otherwise no stimulus for the changes in insulin and glucagon secretion would be present. Thus, when tissue insulin sensitivity changes, a new steady-state glucose level results, at a value somewhere between that expected for the change in insulin action and that expected for the change in pancreatic hormone secretion, with the exact level depending on islet α - and β -cell responsiveness and sensitivity to glucose.

Following food ingestion, plasma glucose excursions are minimized by the islet. This is accomplished by a reduction in hepatic glucose production and an increase in peripheral glucose uptake. These changes in glucose metabolism arise as a result of alterations in insulin and glucagon secretion, which are regulated on a minute-to-minute basis by an interaction between glucose, amino acids, and the gut hormones. Glucose is the key regulator of the islet in this system since it not only regulates insulin and glucagon secretion directly, but it also modulates responses to the other substrates as well as gut hormones and neural factors released during nutrient ingestion (see Chap. 4).

From this description it is clear that when the feedback loop is functional, interpretation of any isolated aspect of this glucose homeostatic mechanism cannot be meaningfully performed without

FIGURE 21-1. A model for the normal steady-state regulation of plasma glucose level. Plasma glucose has direct effects on the pancreas to modulate insulin and glucagon secretion as well as interacting with nonglucose stimuli to modify α - and β -cell responses to these stimuli. During hyperglycemia, insulin secretion is increased and glucagon secretion reduced. When hypoglycemia prevails, glucagon secretion is enhanced and insulin secretion is diminished. Glucagon stimulates hepatic glucose production. Insulin inhibits glucose release by the liver and stimulates glucose use in insulin-sensitive tissues. Glucose uptake by the brain is insulin independent, but in the periphery glucose uptake by fat and muscle is enhanced by insulin. Any change in hormone or substrate concentration or glucose use will be modulated by the loop in order that glucose use and production remain balanced. The plasma glucose level at which this occurs is determined by the efficiency with which the peripheral tissues take up glucose, the rate of hepatic glucose production, and islet α - and β -cell responsiveness to glucose. (Adapted, with permission, from Porte.⁹²)

taking into account all of the participating variables. Thus it is vitally important that comparisons of islet secretory function, hepatic glucose output, or peripheral tissue glucose uptake between different groups of individuals be performed at similar hormonal and substrate levels or that differences in these levels be taken into account. Failure to do so could lead to a gross misinterpretation of the status of these various components of the feedback loop.

PATHOPHYSIOLOGY OF ISLET DYSFUNCTION IN T2DM

Basal Insulin Secretion

Fasting plasma insulin levels in patients with T2DM, as compared with nondiabetic controls, have been reported as low, normal, and elevated.^{6–10} However, as is evident from the closed feedback loop relationship just described, it is important that type 2 diabetic patients be adiposity (insulin resistance)-matched and have their insulin levels evaluated at matched plasma glucose concentrations. Such evaluations have been performed in two ways. Glucose has been infused into normal subjects to match their glucose levels with those of diabetic subjects, and diabetic individuals have had their glucose levels lowered to achieve normoglycemia by means of an insulin infusion followed by an insulin washout period. Under these conditions the resulting steady-state insulin levels in diabetic patients are lower than those of weight-matched and presumably insulin sensitivity-matched controls.^{11,12} Use of such methods has unmasked a deficiency of basal insulin secretion in patients with T2DM.¹³ It appears, therefore, that in T2DM there is a fundamental decrease in β -cell responsiveness to the prevailing plasma glucose level, but that the effect of the resultant hyperglycemia is to stimulate basal insulin output to the point where the

insulin levels will often appear normal or, if insulin resistance is present, may even be higher than those of normal lean subjects.

Insulin release is not simply a continuous process, but rather it has both pulsatile and oscillatory characteristics. Pulsatile insulin secretion has been demonstrated in healthy subjects, with distinct pulses occurring approximately every 10–15 minutes (Fig. 21-2A).¹⁴ These pulses occur on a background of longer oscilla-

FIGURE 21-2. A. Two-hour plasma insulin profile in a healthy nondiabetic subject. From samples drawn every minute, it is apparent that insulin is released in regular pulses every 12–15 min. B. Twenty-four-hour insulin secretion profile in a healthy nondiabetic subject. Meals were eaten at 0900, 1300, and 1800 hours. The arrows indicate statistically significant pulses of secretion occurring approximately every 105–120 minutes during the waking hours (0900–2300 hours) and approximately every 180 minutes in the subsequent 10 hours during sleep. (A. Reprinted with permission from O'Rahilly et al.¹⁴ B. Reprinted with permission from Polonsky et al.¹⁵)

tions with cycles approximately every 120 minutes (Fig. 21-2B).¹⁵ Examination of these patterns reveals both to be abnormal in subjects with T2DM and in individuals at high risk for developing the disease.^{14,16–18} Although the exact cause of these abnormalities has not been determined, it would appear that the derangement in pulsatile secretion is likely to be intrinsic to the pancreatic β cell, since isolated islets have been found to have an intrinsic pacemaker that stimulates pulsatile insulin release *in vitro* with a periodicity similar to that observed *in vivo*.¹⁹

Comparisons of basal insulin secretion in type 2 diabetic subjects and normal individuals may be confounded by the fact that proinsulin cross-reacts in conventional insulin radioimmunoassays. Using a radioimmunoassay specific for insulin, it has been shown that proinsulin and proinsulin intermediates contribute an average of twice as much to basal insulin immunoreactivity (approximately 30%) in subjects with T2DM as in healthy subjects (approximately 15%).^{20–24} Thus depending on the assay the true insulin levels in these patients may be actually lower than those measured as immunoreactive insulin.

Glucose-Stimulated Insulin Secretion

Although measurement of plasma glucose levels during the oral glucose tolerance test provides a method for the diagnosis of T2DM, the use of this test as a means of assessing β -cell function in patients with this disorder is somewhat problematic. This is because it is difficult to control factors such as gastric emptying time, gut hormone secretion rates, and the differences in glucose levels, which are important variables during the test. Thus, although some patients with T2DM will demonstrate an exaggerated insulin response late in the oral test,^{6,7} this seems to be the result of an early deficient response leading to the markedly increased glucose levels that provide both a prolonged and exaggerated stimulus to the β cell.^{25,26} However, the magnitude of the insulin response over the first 30 minutes following oral glucose administration is reduced in both T2DM and impaired glucose tolerance (Fig. 21-3A).²⁶ In fact, in subjects with reduced glucose tolerance, small changes in the magnitude of this response can have dramatic effects on glucose tolerance (Fig. 21-3B).²⁶

Use of an intravenous glucose challenge avoids many of the complicating variables associated with oral glucose tolerance testing. Using this test, T2DM has been shown to be characterized by total absence of the acute or first-phase insulin response measured during the first 10 minutes following intravenous glucose administration (Fig. 21-4). Loss of this response can be documented at a fasting plasma glucose level above 115 mg/dL (6.4 mmol/L; Fig. 21-4).^{27,28} Some individuals with the highest fasting plasma glucose levels have even been observed to have an absolute decrease below basal insulin levels following the administration of an intravenous glucose challenge.²⁹ The insulin response after the first 10 minutes is called the second phase. Like the fasting insulin level, it is a function of the prevailing fasting glucose level. Thus, in subjects whose fasting plasma glucose levels are less than 200 mg/dL (11.1 mmol/L), second-phase insulin responses may appear normal or even increased in some patients with obesity and insulin resistance (Fig. 21-5).¹³ However, when comparisons are made to adiposity-matched normal subjects at equal plasma glucose levels, it is apparent that second-phase insulin secretion is also decreased in type 2 diabetic patients. Once plasma glucose levels rise above 200–250 mg/dL (11.1–13.9 mmol/L), glycosuria ensues, thus preventing a sufficient rise in glucose level to compensate for the

FIGURE 21-3. Ratio of the incremental responses of immunoreactive insulin (Δ IRI) and glucose (Δ G) over the first 30 minutes following oral glucose ingestion in 94 Japanese-American subjects with varying glucose tolerance. **A.** Of the 94 subjects, 56 had normal glucose tolerance, 10 impaired glucose tolerance, and 28 T2DM. Significant decreases in the Δ IRI/ Δ G ($p < 0.0001$) occurred with decreasing glucose tolerance. **B.** Relationship between the ratio of the incremental immunoreactive insulin and glucose responses (Δ IRI/ Δ G) over the first 30 minutes following oral glucose ingestion and glucose tolerance, the latter determined as the incremental glucose area (AUC G) during the oral glucose tolerance test. Subjects with normal glucose tolerance ($\square$), impaired glucose tolerance ($\diamond$), and T2DM ($\blacktriangle$) are indicated. The relationship between these variables is nonlinear with an r^2 value of 0.38 ($p < 0.0001$). (Reprinted with permission from Kahn et al.²⁶)

impaired insulin secretion. Therefore, patients with fasting plasma glucose levels above 250 mg/dL (13.9 mmol/L) are usually absolutely insulin deficient and their second-phase responses are characterized by absolute reductions in insulin release.¹³ These individuals have been termed as having *decompensated type 2 diabetes*.

The regulation of insulin secretion by glucose can also be studied during an oscillating glucose infusion. When the periodicity of the glucose oscillations is varied, the β cell can be stimulated to oscillate in concert with these exogenous glucose cycles.¹⁸ An inability to entrain is another marker of β -cell dysfunction present in subjects with T2DM. This lack of stimulation has also been demonstrated in subjects with impaired glucose tolerance, consistent with an early abnormality of β -cell function in these individuals (Fig. 21-6).¹⁸

FIGURE 21-4. Relation between incremental acute (3- to 5-minute) insulin response and fasting glucose level in normal and type 2 diabetic subjects. (Reprinted with permission from Bounzell et al.¹⁴)

Non-Glucose-Stimulated Insulin Secretion

Administration of one of a variety of nonglucose stimuli, such as the amino acid arginine,¹³ the gastrointestinal hormones secretin³⁰ or glucagon-like peptide 1 (GLP-1),³¹ the β -adrenergic agent isoproterenol,³⁰ or the sulfonylurea tolbutamide,³² is also followed by an acute insulin response.²⁰ In type 2 diabetic patients with a fasting plasma glucose level less than 200 mg/dL (11.1 mmol/L), the acute insulin response to any of these secretagogues is of normal magnitude when subjects are matched for body adiposity

(Fig. 21-7).^{13,30,32} However, as is the case for basal and second-phase insulin secretion, the elevated plasma glucose level appears to be responsible for the maintenance of these apparently normal insulin responses to nonglucose stimuli. When plasma glucose levels are matched by either a glucose infusion in normal subjects or an insulin infusion in type 2 diabetic subjects, the acute insulin response to a nonglucose stimulus is also found to be reduced in diabetic subjects (Fig. 21-8).^{11,33} This regulatory effect of glucose, termed *glucose potentiation*, can be expressed as the slope of the line relating the acute insulin response to a nonglucose secretagogue as a function of plasma glucose level between 100 and 250 mg/dL (5.6 and 13.9 mmol/L). Type 2 diabetic subjects with fasting hyperglycemia have been shown to have a much flatter slope of potentiation than normal individuals.¹¹

At a glucose level above 450 mg/dL (25.0 mmol/L) both normal and diabetic subjects reach their maximal acute insulin responses, termed AIRmax (Fig. 21-8).³³ The observed reduction in maximal responsiveness in diabetic subjects denotes a decrease in insulin secretory capacity. The similarity of the glucose level giving a half-maximal response (PG_{50}) in both diabetic and healthy individuals indicates an equivalent β -cell sensitivity to glucose.³³ However, AIRmax has a curvilinear relationship to the fasting plasma glucose level (Fig. 21-9).³⁴ Thus there is already a reduction of 50–75% in secretory capacity by the time the diagnostic level of hyperglycemia is reached.

Basal and Stimulated Glucagon Secretion

Abnormalities of glucagon secretion have also been demonstrated in T2DM. The normal regulation of glucagon release is not en-

FIGURE 21-5. Insulin release in response to intravenous administration of glucose in normal and type 2 diabetic subjects. Mean fasting plasma glucose concentrations: normal subjects, 85 ± 3 mg/dL (4.7 ± 0.2 mmol/L); diabetic subjects, 160 ± 10 mg/dL (5.9 ± 0.6 mmol/L). Note the relative preservation of the second-phase insulin response in type 2 diabetic subjects. (Reprinted with permission from Pfeiffer et al.¹³)

FIGURE 21-6. Entrainment of insulin secretion by glucose in subjects with normal glucose tolerance (**left panel**), impaired glucose tolerance (**middle panel**), and T2DM (**right panel**). Profiles of the glucose infusion rate, glucose and insulin concentrations, and the derived insulin secretory rates are illustrated for a typical subject from each group. Studies for each individual are shown during a slow oscillatory infusion with periods of 144 minutes. In the control subject, the increase in amplitude of the glucose oscillations is accompanied by an increase in insulin secretory rate oscillations, while in the subjects with impaired glucose tolerance and T2DM, the amplitude of the insulin secretory rate oscillations did not increase with the increase in amplitude of the glucose oscillations. (Reprinted with permission from O'Meara et al.¹⁸)

tirely understood but appears to be dependent on inhibition of the α cell by glucose or insulin alone or by insulin and glucose together (see Chap. 7).³⁵ Bearing this in mind, type 2 diabetic patients with plasma glucose levels below 250 mg/dL (13.9 mmol/L) have been shown to have apparently normal basal plasma glucagon levels.³⁶ Though matching of plasma glucose levels does not pro-

vide evidence as to whether glucose or insulin regulation of the α cell is impaired, it has demonstrated that these normal glucagon levels are inappropriately elevated for the prevailing hyperglycemia.^{33,36}

The glucagon response to an intravenous glucose challenge is also abnormal in type 2 diabetic patients. Although bolus admin-

FIGURE 21-7. Insulin responses to the nonglucose stimulant arginine in normal and type 2 diabetic subjects. Mean fasting plasma glucose concentrations: normal subjects, 85 ± 3 mg/dL (4.7 ± 0.2 mmol/L); diabetic subjects, 172 ± 9 mg/dL (9.6 ± 0.5 mmol/L). The insulin responses to arginine were not statistically different in the two groups. (Reprinted with permission from Pfeifer et al.¹³)

FIGURE 21-8. A comparison of acute insulin responses to 5 g IV arginine (mean 2- to 5-minute insulin increment) at five matched plasma glucose levels in eight patients with T2DM and in eight controls of similar age and body weight. The slope of potentiation is the linear portion of the relation between plasma glucose (100–250 mg/dL, 5.5–13.9 mmol/L) and the acute insulin response. It is much flatter in the diabetic group. The maximal insulin response, a measure of β -cell secretory capacity, is the response at a glucose concentration greater than 450 mg/dL (25 mmol/L). It is also much lower in the diabetic group. The half-maximal glucose level, a measure of glucose sensitivity of the β cell, is between 150 mg/dL (8.3 mmol/L) and 200 mg/dL (11.1 mmol/L) and is unchanged in the diabetic group. (Reprinted with permission from Ward et al.³³)

istration of intravenous glucose results in normal suppression of glucagon release, this suppression is a slow phenomenon. Although there may be less insulin present, glucose disposal rates are lower and therefore a higher glucose level prevails, causing only what appears to be a normal suppressive response. That this is indeed the case is demonstrated by the fact that during a glucose infusion, glucagon levels are elevated at a variety of matched glucose levels in type 2 diabetic subjects as compared to controls.³³ In addition, the magnitude of the acute glucagon response to amino acid stimulation is greater at all glucose levels in type 2 diabetic subjects (Fig. 21-10).³³ This is consistent with an abnormality in glucose and/or insulin regulation of α -cell secretory function.

Assessment of α -cell secretory function by oral glucose tolerance testing is, as in β -cell evaluation, confounded by the inability to control the plasma glucose level, the rate of gastric emptying, and gut peptide secretion. Despite these caveats, when oral testing is performed, defects in α -cell function are often more apparent than β -cell defects. Following carbohydrate ingestion, a gross abnormality in glucagon secretion is apparent in type 2 diabetic subjects, who may even demonstrate a paradoxical increase rather than the usual suppression observed with hyperglycemia.³⁷ Furthermore, ingestion of a pure protein meal produces an exaggerated

FIGURE 21-9. Curvilinear relationship between β -cell secretory capacity (AIRmax) and fasting plasma glucose in nine subjects with T2DM (●) and ten subjects with normal glucose tolerance (○). There is a broad range of β -cell secretory capacity in the healthy subjects due to large differences in insulin sensitivity while in the subjects with T2DM, the range is narrower as a manifestation of the impaired islet function. The nonlinear relationship between these two parameters ($r = -0.76$; $p < 0.0001$) demonstrates that the degree of β -cell function is a determinant of the fasting glucose level. This relation predicts that a relatively large initial loss of β -cell function should result in only a small increase of fasting plasma glucose level. However, further small declines in β -cell function would lead to much larger increases of glucose level. (Adapted from Røder et al.⁴⁴)

glucagon response in type 2 diabetic patients regardless of whether their fasting glucose levels are normal or elevated.³⁸

Thus it appears that an abnormality in α -cell function is present in most patients with T2DM. At the present time, however, it is unclear whether this abnormality results from reduced insulin regulation of the α cell, diminished glucose sensing, or a combination.

FIGURE 21-10. A comparison of acute glucagon responses to arginine as a function of glucose level in eight normal subjects and in eight patients with T2DM. (Reprinted with permission from Ward et al.⁴⁴)

Nature of the Islet Lesion in T2DM

Although it is clear that islet dysfunction is present in T2DM, it is still not certain whether the defects in insulin secretion are the result of a reduction of β -cell mass, dysfunction of a normal number of β cells, or some combination. In addition, as the normal physiologic regulation of glucagon secretion is incompletely understood, the contribution of the β -cell defect to α -cell dysfunction is also not entirely clear.

Examination of β -cell mass, islet size, and islet characteristics in postmortem studies of type 2 diabetics have been performed by a number of investigators. Direct quantification of β -cell mass is difficult due to postmortem changes, but most studies have demonstrated that the islets in affected individuals are smaller and that β -cell mass is decreased by 40–60% compared to appropriately matched nondiabetic subjects.³⁹ Although islet size is reduced, it appears that this loss of volume is due purely to the change in β -cell mass since no significant reduction in α , δ , and PP cells has been documented in T2DM. Although the precise etiology of this β -cell mass reduction is unknown, changes in islet morphology, including islet fibrosis and amyloid deposition, have been demonstrated,³⁹ the latter evidently due to deposition of a second β -cell-specific peptide called islet amyloid polypeptide (IAPP) or amylin.^{40,41} IAPP may be a significant factor in the pathogenesis of the β -cell loss of T2DM in that the amyloid deposits appear to replace the β cells specifically (see Chap. 17). Although the human peptide has a predilection to form amyloid at high concentrations *in vitro*,⁴² the mechanism underlying its propensity to deposit in the islets of individuals with T2DM is not understood. The peptide is normally cosecreted with insulin,⁴³ but it does not appear that simple overproduction under conditions of increased β -cell secretory demand can explain amyloid formation, as obese individuals without diabetes are no more likely to have amyloid than lean subjects. Furthermore, studies in transgenic mice overproducing human IAPP failed to demonstrate amyloid⁴⁴ until they were treated with a high-fat diet⁴⁵ or were made markedly insulin resistant by crossbreeding them with lines of genetically modified insulin-resistant mice.^{46,47} Perhaps the demonstration in neonatal rat islet cultures⁴⁸ and isolated human islets⁴⁹ of a dissociation of insulin and IAPP secretion due to the isolated release of IAPP through the constitutive secretory pathway,⁴⁸ the finding of amyloid fibrils in transgenic islets expressing human IAPP exposed to severe hyperglycemia *in vitro*,⁵⁰ the toxic effect of amyloid fibrils,^{42,51} and the presence of other components such as the heparan sulfate proteoglycan perlecan^{52,53} may be important clues to the mechanism(s) underlying islet amyloid formation.

Although it is difficult to evaluate the effect of a 50% reduction of β -cell mass in humans; an animal study suggests that this amount of cell loss alone is insufficient to result in fasting hyperglycemia and the insulin secretion abnormalities observed in T2DM.⁵⁴ Therefore, it appears that the development of fasting hyperglycemia and defective secretory responses requires either a greater loss of β -cell mass or a 50% reduction in mass along with dysfunction of the remaining cells or insulin resistance.

In an attempt to clarify whether larger degrees of β -cell loss can reproduce the features of T2DM, animal models have been created by either pancreatectomy or neonatal administration of streptozocin. Removal of two-thirds of a canine pancreas does not result in fasting hyperglycemia, nor is the classic loss of first-phase insulin release observed.⁵⁴ Although the insulin response to non-

glucose secretagogues is present, at matched glucose levels the magnitude of this response is reduced, as is the slope of glucose potentiation, indicating that this measure is a sensitive indicator of β -cell mass reduction. In rodents, a 60% pancreatectomy had similar effects, with an unchanged fasting glucose level and a reduced glucose potentiation slope.⁵⁵ Only when islet mass was reduced by 90% were hyperglycemia and insulin secretory responses similar to those observed in T2DM seen.^{56,57} However, α -cell function could not be tested due to the marked reduction in glucagon secretion, implying that this model does not precisely replicate the islet lesion of T2DM. With neonatal streptozocin administration, abnormal glucose-regulated α -cell secretion has been demonstrated, but the glucagon response to arginine is unlike that of T2DM in that the magnitude of the response is reduced, rather than increased, when compared to controls.⁵⁸ This same model of β -cell mass loss is associated with a loss of first-phase insulin secretion, but the response to arginine administration does not simulate that observed in type 2 diabetes,⁵⁹ in that it is increased at low glucose concentrations and reduced at high glucose levels. Thus, neither surgical reduction of β - and α -cell mass nor cytotoxic β -cell destruction can produce an exact model of the insulin- and glucagon secretory abnormalities found in human T2DM.

Models of islet dysfunction have been created in normal human subjects by the prolonged administration of cyclic somatostatin or an analogue of this peptide. When normal human subjects received a cyclic somatostatin infusion together with glucagon replacement for 2 days, the observed metabolic derangements were fairly similar to those in type 2 diabetic subjects: fasting hyperglycemia with near-normal basal insulin levels, markedly diminished first- and second-phase insulin responses to glucose, a preserved insulin response to a nonglucose secretagogue, and increased glucose turnover.^{3,59} Healthy individuals who were treated for 8 days with a somatostatin analogue without glucagon replacement also developed fasting hyperglycemia, markedly impaired first- and second-phase responses to glucose, and a preserved insulin response to arginine.⁶⁰ However, this latter study demonstrated that although the β -cell dysfunction produced by somatostatin closely mimics many of the features of T2DM, the mechanism by which it does this is different. β -Cell secretory capacity (AIR_{max}) remains unchanged while the sensitivity to glucose (PG₅₀) is impaired—the reverse of T2DM. Whether some combination of the type of islet dysfunction produced by somatostatin together with a reduction in islet mass can duplicate the α - and β -cell defects of T2DM is as yet unknown.

The theory that overactivity of the α -adrenergic component of pancreatic sympathetic innervation could also contribute to the pathogenesis of T2DM has been suggested by the finding that phentolamine, which blocks the α -adrenergic system, can partially restore the acute insulin response to glucose and the ability of glucose to potentiate insulin secretion in these patients.^{61,62} However, similarly to somatostatin, elevated catecholamines do not change β -cell secretory capacity (AIR_{max}) but impair β -cell sensitivity to glucose (PG₅₀).⁶³ Furthermore, the mildly elevated catecholamine levels documented in some diabetic subjects offer additional support for enhanced activity of the α -adrenergic nervous system under some conditions (see Chap. 8).⁶¹ Two other inhibitory peptides, galanin and pancreastatin, have been isolated in pancreatic tissue.^{64,65} Galanin has been demonstrated in pancreatic sympathetic nerves in dogs.⁶⁴ Intravenous administration of these peptides increases glucose levels, inhibits insulin secretion, and stimulates

glucagon release.^{64,65} Because these peptides can simulate the islet secretory changes that characterize T2DM, it was proposed that increased intrapancreatic concentrations or islet sensitivity to either of these peptides may be present in T2DM. However, evidence suggests that galanin is not effective in primates or humans.⁶⁶ Thus, some other peptide would need to be involved for this mechanism to be operative. IAPP has been suggested as an alternate peptide with this function, and some studies suggest that IAPP impairs insulin release.⁶⁷ This impairment has not been a universal finding, and at present it appears unlikely that physiologic levels of IAPP modulate β -cell function.⁶⁷ Enhanced endogenous prostaglandin effects may also contribute to diminished β -cell function, as suggested by the increase in first- and second-phase insulin responses to intravenous glucose and the increase in glucose potentiation slope observed in type 2 diabetic subjects who received an intravenous infusion of the prostaglandin synthesis inhibitor sodium salicylate.^{68,69}

A number of studies have demonstrated that hyperglycemia not only may induce structural damage to the islet, but also can reproduce some of the secretory findings of T2DM. Following partial pancreatectomy in rats, the islet remnant often regenerates with new islet tissue also developing from pancreatic ductal tissue.⁷⁰ However, the new tissue comprises not only normal-appearing islets but also islets that are disorganized and fibrotic.⁵⁶ These changes in islet structure appear to be the result of hyperglycemia, because the development of these histologic abnormalities can be prevented by insulin treatment.⁷¹ Mild chronic hyperglycemia produced by a continuous glucose infusion is capable of altering islet function, resulting in a loss of glucose-stimulated insulin release, and when hyperglycemia becomes more severe, a loss of the potentiating effect of glucose.⁷² The combination of a 60% pancreatectomy and 6 weeks of mild chronic hyperglycemia produces not only a loss of glucose potentiation as is seen after β -cell mass reduction alone, but also an impairment of glucose-stimulated insulin secretion.⁵⁵ Although these studies addressed the effects of mild prolonged increases in plasma glucose concentrations, more recent animal studies have demonstrated that marked hyperglycemia produced by intravenous glucose administration to healthy animals results in changes in β -cell function as early as 14 hours after commencing the infusion.⁷³ In addition, animals given phlorizin, an agent capable of lowering the glucose level by inhibiting renal tubular cell reabsorption of glucose, demonstrate a decline in plasma glucose levels and a restoration of β -cell function toward normal.⁵⁷ These studies add credence to the idea that hyperglycemia is a cellular toxin or leads to suppression of islet function and may therefore contribute to the pancreatic defect observed in T2DM.

Recently, work has focused on the potential adverse effects of dietary fat and free fatty acids on islet function. Consumption of a high-fat diet is associated with an increased risk of developing diabetes that is related in part to the obesity and associated insulin resistance that develops with the increased caloric intake, but may also be the result of alterations in β -cell function that occur.^{74,75} It is unclear what period of time is required for these changes to occur but it is clear that altering the balance of the diet to more carbohydrate results in an improvement in glucose tolerance within a period as short as 3 days.⁷⁶⁻⁷⁸ Free fatty acids have also been shown to have a negative impact on islet function because prolonged incubation of islets with free fatty acids *in vitro* results in a reduction in insulin secretion, with changes in proinsulin mRNA levels and insulin biosynthesis also having been demonstrated.⁷⁹⁻⁸¹

Furthermore, in the presence of both glucose and free fatty acids, neutral lipid accumulation occurs within islets,⁸² with increased quantities of this morphologic change being observed with aging.⁸³ Whether this change is even greater in type 2 diabetes and whether it impacts islet function or is simply a marker of such are presently unknown.

As mentioned, other evidence for β -cell dysfunction in T2DM is a change in the proportion of circulating proinsulin, the circulating insulin precursor. Under basal conditions, about 15% of insulin-like immunoreactivity measured by conventional insulin radioimmunoassays is comprised of proinsulin and its conversion intermediates des 31,32 and des 64,65 proinsulin.⁸⁴ This proportion is doubled in subjects with T2DM,^{21-23,84} with the vast majority of circulating proinsulin-like molecules being intact proinsulin and the conversion intermediate des 31,32 proinsulin.²⁴ This increase in type 2 diabetic subjects appears to represent a fundamental change in the production of insulin from its precursor proinsulin. Although no single study has been able to identify the mechanism(s), a number of studies suggest that defective processing of proinsulin to insulin may be the underlying basis for the observed differences. Administration of glucocorticoids and growth hormone to humans,^{84,85} as well as the induction of a subclinical defect in β -cell function in nonhuman primates with streptozocin,⁸⁶ has resulted in disproportionate proinsulinemia. Although it is possible that the ability of the β cell to normally process proinsulin may be limited and that an increase in secretory demand may result in the release of a granular pool that has not had sufficient time to cleave proinsulin to insulin, data from studies in healthy insulin-resistant humans would not support this concept. Thus, neither obesity^{22,23,87} nor insulin resistance induced experimentally with nicotinic acid⁸⁸ induces disproportionate proinsulinemia. Furthermore, women with a history of gestational diabetes have been demonstrated to have disproportionate proinsulinemia following pregnancy even though their glucose tolerance has returned to normal.⁸⁹ Japanese-American men with normal or impaired glucose tolerance who developed T2DM after 5 years of observation have disproportionately increased proinsulin levels at baseline when compared to subjects who do not progress to T2DM,⁹⁰ suggesting that this defect is present early in the course of the development of T2DM. A similar observation has been made in older Finnish subjects.⁹¹

From the foregoing discussion it is apparent that although many different perturbations can reproduce some features of the β -cell secretory abnormalities observed in T2DM, no single experimental approach has been able to fully replicate the findings of this disorder. This suggests the possibility that the abnormalities of islet function characteristic of T2DM are the result of a combination of a variety of lesions and supports the concept that considerable heterogeneity is probably involved in the pathogenesis of the β -cell defects of this disorder.⁹²

PATHOPHYSIOLOGY OF INSULIN RESISTANCE AND GLUCOSE RESISTANCE IN T2DM

Tissue resistance to insulin is an important component of the glucose intolerance of T2DM (see Chap. 22). Rare syndromes of extreme insulin resistance associated with diabetes mellitus and acanthosis nigricans have been described in which genetic defects in insulin receptor function are present,⁹³ as has a syndrome of ex-

treme insulin resistance with diabetes as a result of a dominant negative mutation in the peroxisome proliferator activated receptor gamma (PPAR- γ).⁹⁴ The etiology of defects in insulin action observed in the liver and peripheral tissues of the more common forms of type 2 diabetes is much less clear. However, it does appear that a major component of this abnormality may be related to obesity, with central fat distribution, and particularly intra-abdominal fat, being important.⁹⁵⁻⁹⁷ The recent elucidation of the importance of glucose-mediated glucose disposal to glucose tolerance requires that its role in the pathophysiology of T2DM also be considered.

Hepatic Insulin Resistance

Basal rates of hepatic glucose production in patients with T2DM have been documented as normal or increased.⁹⁸⁻¹⁰⁰ As with measurements of insulin secretion, it is important that these production rates be evaluated in the context of the glucose concentration at which they were measured. When this is done, it is apparent that even the "normal" values are inappropriately elevated for the ambient glucose level. In many studies, the degree of the abnormality in hepatic glucose output is positively correlated with the degree of fasting hyperglycemia, suggesting that the rate of hepatic glucose production is an important determinant of the fasting plasma glucose level (Fig. 21-11).

The increased rate of hepatic glucose production results from an impairment of the effects of insulin and glucose to normally suppress glucose release by the hepatocyte. A shift to the right in the insulin dose-response curve with no reduction in the maximal suppressive response at supraphysiologic insulin levels has been demonstrated in diabetic subjects studied at euglycemia.¹⁰¹ This type of change is compatible with a reduction in hepatic sensitivity to insulin produced by a decrease in insulin receptor number. However, when similar studies are performed in type 2 diabetic subjects at basal hyperglycemia, maximal suppression of hepatic glucose

production occurs at lower insulin levels, but the dose-response relation still demonstrates a defect in insulin action when compared to control subjects studied at normoglycemia.¹⁰⁰ Thus hyperglycemia appears capable of exerting a suppressive effect on hepatic glucose output independent of insulin, but is unable to fully compensate for the reduction in insulin sensitivity found in T2DM. This suggests that a defect in the ability of glucose to inhibit its own release from the liver is also contributing to the observed glucose overproduction in the basal state. Glucagon, of major importance in the maintenance of postabsorptive hepatic glucose release,^{4,5} appears to be capable of maintaining more than half of the hepatic glucose production observed in T2DM.¹⁰² As a result, the abnormal regulation of glucagon secretion in these subjects may help explain the observed hepatic resistance of type 2 diabetics to the suppressive effects of both insulin and glucose.

During oral intake the liver plays a critical role in the maintenance of glucose homeostasis. The meal-induced alterations in the concentrations of glucose, insulin, and glucagon entering the liver through the portal circulation contribute to the liver changing from its status in the fasted condition as an organ responsible solely for glucose production to one that, during refeeding, restores its glycogen content by increasing its uptake and/or synthesis of glucose. Therefore, considering the defects in hepatic sensitivity to glucose and insulin, it is not surprising that following an oral glucose load a delayed reduction in hepatic glucose production can be demonstrated in T2DM.^{8,103} This failure of the liver to adequately suppress its glucose production accounts for a considerable proportion of the observed rise in plasma glucose concentrations following meal ingestion. Although a large proportion of this defect in suppression of hepatic glucose release may result from the deficient insulin response, neither the contribution of the increased glucagon response during meals nor the potential for variability in hepatic sensitivity to other neurohormonal responses following oral intake has yet been defined.

FIGURE 21-11. Correlation between fasting plasma glucose levels and glucose production rate in 20 patients with untreated T2DM. Despite the suppressive effect of hyperglycemia on glucose production, those patients with the highest glucose levels had the highest production rates. (Reprinted with permission from Best et al.⁹⁸)

Peripheral Insulin Resistance

Using the euglycemic insulin clamp technique, it has been conclusively demonstrated that a reduction of more than 55% in the mean glucose disposal rate exists in subjects with T2DM.¹⁰¹ Further analysis of the *in vivo* dose-response relation suggests that this reduction in insulin responsiveness is the result of two abnormalities (Fig. 21-12A). First, the rightward shift in the curve is compatible with a reduction in cellular insulin receptor number. A decrease in receptor number has been reported in *in vitro* studies using monocytes,¹⁰⁴ erythrocytes,¹⁰⁵ and adipocytes.¹⁰¹ Despite the presence of spare or unoccupied receptors, the marked decrease in the maximal rate of glucose disposal suggests the existence of a second defect in peripheral insulin action, namely, a postbinding (intracellular) defect.¹⁰¹ Insulin-binding studies on isolated adipocytes from individuals with T2DM have shown that the predominant determinant of the severity of the peripheral insulin resistance in untreated patients is this reduction in postbinding insulin action.¹⁰¹ Initial analysis suggested that part of this defect in intracellular insulin action resulted from a reduction in the number of glucose transporters.¹⁰⁶ However, it appears that the total amount of GLUT-4 mRNA and protein is normal although the function or the intracellular movement to the cell membrane of this insulin-dependent glucose transporter may be diminished (see Chap. 22).¹⁰⁷ Assessments of a number of the key molecules involved in intracellular transmission of the insulin signal following insulin binding to its receptor (e.g., insulin receptor substrate-1 [IRS-1] and phosphoinositol 3

kinase [PI3 kinase]) have demonstrated defects in the action of some of these molecules, but these changes are not distinct from those observed in obesity.^{108,109}

These preceding observations of reduced insulin effectiveness were all made under euglycemic conditions and thus do not take into account the ability of glucose, by virtue of mass action, to augment its own disposal into the peripheral tissues.^{110,111} When incremental insulin dose-response studies are performed at the basal level of hyperglycemia in type 2 diabetic subjects, the relation of insulin's effect on peripheral glucose disposal is essentially identical to that observed in matched control subjects studied at euglycemia (Fig. 21-12B).¹⁰⁰ These findings suggest that in the presence of hyperglycemia, any impairment of peripheral insulin action is overcome by a mass action increase of glucose uptake. Therefore, as glucose levels rise due to the increase in hepatic glucose production, peripheral glucose uptake increases by mass action so that a new steady state is created in which the increased glucose levels are associated with increased glucose use despite the impairment of insulin action.

The efficiency of glucose uptake following oral glucose ingestion is also defective in type 2 diabetic subjects. In the peripheral tissues, ingested glucose normally undergoes oxidative and non-oxidative metabolism, with the rate of these processes being controlled by the enzymes pyruvate dehydrogenase and glycogen synthase, respectively. At low insulin concentrations the major route of peripheral glucose disposal is via glucose oxidation, while at higher levels disposal occurs predominantly by glycogen synthesis.¹¹² In

FIGURE 21-12. A. Mean dose-response curves for insulin-stimulated peripheral glucose disposal in control subjects ($\bullet$), subjects with impaired glucose tolerance ($\circ$), and nonobese ($\blacktriangle$) and obese ($\blacksquare$) type 2 diabetic subjects. Note the large reduction in maximum glucose disposal in the diabetic subjects. B. The effect of hyperglycemia on the dose-response relation for insulin-stimulated peripheral glucose disposal: normal subjects at euglycemia ($\bullet$), type 2 diabetic subjects at hyperglycemia ($\blacktriangle$), and type 2 diabetic subjects at euglycemia ($\blacksquare$). Note the similarity of glucose uptake at spontaneous levels of glycemia. (A. Reprinted with permission from Kolterman et al.¹⁰¹ B. Reprinted with permission from Revers et al.¹⁰⁰)

T2DM, the efficiency of glucose uptake by both processes is reduced, with the predominant abnormality being a defect in non-oxidative glucose storage.¹¹³ As glycogen synthase activity is stimulated by insulin, the diminished insulin sensitivity compounded by the reduced insulin secretory response to meals leads to a failure to stimulate normal enzyme activity.¹¹⁴

Glucose Resistance

Besides insulin resistance and islet dysfunction as causes of decreased glucose tolerance, insulin-independent glucose uptake or glucose-mediated glucose uptake is an important factor determining glucose use. In fact, about 80% of tissue glucose uptake in the fasting state occurs by insulin-independent mechanisms, primarily into the brain, but glucose uptake also takes place in muscle, fat, and other tissues.¹¹⁵ During intravenous glucose tolerance testing, glucose-mediated glucose uptake, also known as glucose effectiveness, is important in determining the rate of glucose disappearance.¹¹⁶

Glucose-mediated glucose uptake has been quantified using a number of methods,^{115,116} and has been shown to be regulated in normal subjects^{31,60} and abnormal in patients with type 2 diabetes.¹¹⁷ As suggested in the foregoing discussions of hepatic and peripheral insulin resistance, glucose-mediated glucose disposal is important in decreasing glucose production by the liver and increasing glucose uptake in muscle. Thus it could be envisaged that in type 2 diabetes, glucose resistance would result in a reduced ability of the liver to suppress glucose production and/or a decrease in the effectiveness of peripheral tissues to take up glucose by mass action, thereby contributing to hyperglycemia.

The cellular processes underlying alterations in glucose effectiveness have not been fully elucidated. This function could be dependent on glucose transporter number and/or activity as well as processes involving glucose metabolism after its entry into the cell. These posttransport processes could include regulation of enzymes responsible for glucose use, as well as others that may regulate glucose transporter function such as the enzyme glucosamine fructose amino transferase (GFAT), which metabolizes glucose through a shunt from the glycolytic breakdown process.¹¹⁸ Although glucose effectiveness is independent of a sudden change in insulin level, this process can apparently be regulated by changes in circulating insulin over time. Up until now, all conditions in which glucose effectiveness has been shown to be reduced have been associated with impaired islet function and therefore associated with reduced circulating basal and stimulated insulin levels.^{60,117,119} This finding suggests that improvements in insulin secretion should be associated with an increase in glucose effectiveness, a hypothesis that has yet to be tested. Based on the demonstration that a short infusion of GLP-1 results in an enhancement of glucose effectiveness without a change in basal plasma insulin concentrations,³¹ it would appear that other hormones may also be important in regulating this function.

Role of Obesity, Counterregulatory Hormone Secretion, and Insulin Deficiency

It has long been recognized that obesity is associated with insulin resistance. In the absence of carbohydrate intolerance, dramatic compensatory hyperinsulinemia is present.^{120,121} Though this adaptive response effectively maintains normoglycemia in more than 85% of obese individuals, these elevated plasma insulin levels may

contribute to the alterations in insulin action that are a feature of obesity. With mild degrees of obesity, the predominant change is a reduction in tissue insulin binding.¹²² As body weight and fat cell size increase further, a proportional increase in basal insulin secretion occurs.¹²³ These changes are associated with the development of a postreceptor defect, the severity of which is related to the change in body weight and plasma insulin concentration.¹²⁴ Because central adiposity rather than lower body adiposity is the major determinant of the insulin resistance of obesity,^{123,125} and intra-abdominal fat appears to be an important determinant of insulin sensitivity,⁹⁵⁻⁹⁷ there are also great difficulties in estimating the role of obesity in the insulin resistance of any particular type 2 diabetic person (see Chap. 23). The differences in estimations of adiposity and the corrections applied by some investigators for age differences probably contribute to the controversy in the literature regarding obesity and its role in the insulin resistance of T2DM. Nevertheless, because more than 80% of type 2 diabetic subjects are obese, their elevated basal insulin levels are a manifestation of their diminished insulin sensitivity, which is at least partly the result of their obesity.

Secretion of counterregulatory hormones has been shown to be altered in some patients with T2DM. Increased diurnal fluctuations of plasma growth hormone concentration¹²⁶ and enhanced responses to exercise¹²⁷ have been reported. Basal growth hormone levels, on the other hand, are usually normal except in those patients who are severely hyperglycemic.¹²⁸ Marked hyperglycemia by inducing glycosuria and resultant volume depletion leads to baroreceptor stimulation and increased sympathetic nervous system activation, which would explain the increased levels of catecholamines observed in type 2 diabetic subjects.⁶¹ This effect is more marked as hyperglycemia becomes more severe due to greater urinary glucose losses. Thus, hyperglycemia acts as a stimulus for a neuroendocrine stress response, which leads to counterregulatory hormone secretion. This excessive catecholamine release in turn impairs islet function, and reduces both insulin-mediated and glucose-mediated glucose disposal,¹²⁹⁻¹³¹ thus producing more hyperglycemia (see Chap. 8). Although treatment to lower plasma glucose can return these levels toward or even to normal, more subtle abnormalities of many of these counterregulatory hormones have been reported in subjects with relatively mild hyperglycemia in whom a neuroendocrine stress response as a result of baroreceptor stimulation seems unlikely.¹³² Since counterregulatory hormones are all capable of producing insulin resistance, it appears that even the mild increase in plasma concentrations of such hormones observed in type 2 diabetes patients could contribute to their insulin resistance. With severe hyperglycemia it is likely that the more pronounced neuroendocrine abnormalities contribute to the greater degrees of insulin and glucose resistance observed with poorer glycemic control.

A variety of studies suggest that insulin deficiency, or the metabolic derangements arising from it, is involved in the development of insulin and glucose resistance. Animal studies in which insulin deficiency has been created using agents toxic to the β cell, such as streptozocin, have demonstrated the existence of an abnormality in insulin action. This defect is apparent in *in vitro* studies using adipocytes¹³³ and in the intact animal in the presence of high concentrations of plasma insulin and only trivial elevations in the glucose level.¹³⁴ Although it could be argued that this effect is a result of a direct action of the agent on insulin-sensitive tissues, a similar degree of insulin resistance has been observed in animals following a 90% pancreatectomy.¹³⁵ Demonstration of this relation in type 2

diabetic individuals is more difficult in view of the complicating effects of obesity and residual insulin secretion. However, indirect support for this concept can be obtained from other human studies. First, type 1 diabetic subjects who are totally insulin deficient are insulin resistant.¹³⁶ Second, both type 1 and type 2 diabetic subjects increase their rates of glucose disposal with an amelioration of the postreceptor defect in insulin action when treated with insulin.¹³⁷⁻¹³⁹ Third, states of glucose resistance have been associated with an absolute or relative reduction of β -cell function. For example, type 1 diabetic subjects who have absent insulin responses have reduced glucose effectiveness.¹⁴⁰ In addition, impaired insulin responses produced by somatostatin or epinephrine administration are associated with reduced glucose effectiveness in humans and animals,^{60,141} and β -cell mass reduction with streptozocin in dogs has also been associated with reduced efficiency of glucose-mediated glucose disposal.¹¹⁹ Thus, even though integrated 24-hour plasma insulin levels may be within the normal range in type 2 diabetics, for their degree of hyperglycemia they are relatively insulin deficient and it is this relative hypoinsulinemia that may at least in part be responsible for the observed changes in the efficiency of tissue glucose uptake. From the foregoing discussion it is apparent that the simultaneous presence and interaction of obesity, excessive counterregulatory hormone effects, and the metabolic events related to hypoinsulinemia contribute significantly to the diminished insulin and glucose sensitivity of T2DM. The inability to control for all these factors makes it difficult to discern whether a primary alteration in insulin or glucose action exists in this disease. However, by virtue of its relation with islet function, it is clear that insulin and glucose resistance are of major importance in determining the degree of the metabolic derangement present in T2DM.

THE INTERACTION BETWEEN INSULIN RESISTANCE AND INSULIN SECRETION IN T2DM

The feedback loop comprising the liver, pancreas, and peripheral tissues requires that islet function be an important determinant of the basal glucose level. If islet responsiveness to glucose is high,

then changes in insulin action will not perturb the plasma glucose level very much. Thus in the presence of normal islet function, isolated insulin resistance does not usually result in the development of fasting hyperglycemia. A common condition that exemplifies this is obesity in which the majority of subjects are insulin resistant, but do not have impaired glucose tolerance or diabetes. This lack of change in fasting glycemia is because there is a reciprocal and proportionate increase in insulin secretion, representing an adaptive phenomenon by the normal β cell to insulin resistance (Figs. 21-13 and 21-14A).¹⁴² From percentile charts based on data from healthy subjects, it is possible to determine the adequacy of insulin secretion for the degree of insulin sensitivity (Fig. 21-14B-D). Where the relationship places an individual in a low percentile, this would be predicted to be associated with reduced glucose tolerance.

Further support for the capability of normal islets to adapt their responsiveness is the finding that normal-weight individuals made insulin resistant with nicotinic acid for a period of 2 weeks demonstrate an increase in basal as well as glucose- and non-glucose-stimulated insulin secretion,⁸⁸ and that a decrease in these same measures of β -cell function in individuals who have had an improvement in insulin sensitivity following a 6-month endurance exercise training program.¹⁴³ The enhanced insulin secretion observed under conditions of natural and experimental insulin resistance results from an increase in β -cell secretory capacity without any change in β -cell sensitivity to glucose, while the decreased insulin release that occurs with the exercise-induced improvement in insulin sensitivity results from a decrease in β -cell secretory capacity and no change in β -cell sensitivity to glucose. Furthermore, with experimental insulin resistance basal and stimulated glucagon levels are reduced, providing evidence for α -cell adaptation to prolonged insulin resistance in normal subjects. Although the exact mediator responsible for this alteration in α - and β -cell function has not been identified, evidence in normal subjects suggests that glucose may be responsible for this change. When healthy individuals are given glucose infusions for 2-3 hours, they demonstrate enhanced insulin-secretory responses to a later intravenous glucose challenge despite the fact that glucose levels under both the basal and postinfusion conditions are similar at the time of the test.¹⁴⁴

FIGURE 21-13. Relationship between insulin sensitivity and fasting insulin in 93 healthy subjects (55 males [●] and 38 females [□]). The best fit of the relationship is described by a hyperbolic function (i.e., insulin sensitivity times fasting insulin is a constant). The 5th, 25th, 50th, 75th, and 95th percentiles for the relationship are illustrated. (Reprinted with permission from Kahn et al.¹⁴²)

FIGURE 21-14. A. Relationship between insulin sensitivity and the first-phase insulin response (AIRglucose) in 93 healthy subjects (55 males [●] and 38 females [□]). The best fit of the relationship is described by a hyperbolic function (i.e., insulin sensitivity times first-phase insulin response is a constant). The 5th, 25th, 50th, 75th, and 95th percentiles for the relationship are illustrated. B. Percentile lines for the relationship between insulin sensitivity and the first-phase insulin response (AIRglucose). Data from three studies^{69,145,146} are plotted. Individual data for a former gestational diabetic (**former GDM**) and a control individual (**control for GDM**)¹⁴¹ demonstrate that although β -cell function may be greater in absolute terms, when evaluated relative to the degree of insulin sensitivity, the response is inappropriately low in the former GDM, compatible with β -cell dysfunction. Mean data show that exercise training (ET) in older males¹⁴⁶ does not alter the relationship between insulin sensitivity and the first-phase insulin response, and thus glucose tolerance does not change. In contrast, nicotinic acid (NA)-induced insulin resistance in young males¹⁰⁹ results in a change in the relationship between insulin sensitivity and the first-phase insulin response, which is associated with a reduction in glucose tolerance. C. Percentile lines for the relationship between insulin sensitivity and the first-phase insulin response (AIRglucose) based on data from 93 normal subjects.¹⁴² Mean data from six other studies are plotted. The 10 subjects with type 2 diabetes are insulin resistant and have markedly impaired insulin secretion.¹¹⁷ Thirteen healthy older subjects demonstrate that aging is associated with insulin resistance and a reduction in β -cell function.¹⁴³ Reduced β -cell function is also manifest in 8 women with a history of gestational diabetes (GDM),³¹² 11 women with polycystic ovarian disease (PCO) and a family history of T2DM,³¹³ 21 subjects with impaired glucose tolerance (IGT),¹⁷⁰ and 14 subjects with a first-degree relative with T2DM.³¹⁴ The reduction in β -cell function in these latter three groups is compatible with their high risk of subsequently developing T2DM. D. Individual measurements of insulin sensitivity and the first-phase insulin response (AIRglucose) in a group of first-degree relatives of subjects with T2DM from three different families indicated by different symbols. These individuals, studied when their fasting glucose levels were normal, exhibit broad ranges of both insulin sensitivity and first-phase insulin response. When these two parameters are assessed together, it is apparent that some individuals have well-preserved β -cell function while others have markedly deficient responses and thus would be predicted to be at very high risk of developing hyperglycemia. (A and B. Reprinted with permission from Kahn et al.¹⁴² C. Reprinted with permission from Vidal J, Kahn SE: Regulation of insulin secretion in vivo. In: Lowe WL Jr, ed. Genetics of Diabetes Mellitus. Kluwer;2001;109. D. Reprinted with permission from Kahn SE: Regulation of beta-cell function in vivo: From health to disease. Diabetes Rev 1996;4:372.

When studies of islet secretory function are performed following a 20-hour glucose infusion, consistent increases in the slope of glucose potentiation provide evidence of β -cell adaptation, while consistent decreases in the acute glucagon responses suggest adaptation of α -cell function.¹⁴⁵ Thus it appears that the normal pancreatic islets possess an adaptive capability involving both the α and β cells, and that this adaptation, which may be mediated by changes in glucose level, prevents the development of marked hyperglycemia in individuals with insulin resistance and normal islet function (Fig. 21-15). However, when β -cell dysfunction is present, hyperglycemia will be the expected compensatory response.

When insulin sensitivity is normal, it is unclear what degree of β -cell mass reduction is necessary before fasting hyperglycemia occurs. Some individuals do not develop diabetes mellitus after 70–90% pancreatectomies.^{146,147} Whether this or lesser degrees of β -cell loss are associated with clinically significant hyperglycemia if insulin resistance develops is as yet undetermined. Because this question cannot be easily addressed in humans, mathematical modeling has been utilized to predict the various degrees of β -cell loss and insulin resistance required to produce fasting hyperglycemia.¹⁴⁸ Such modeling predicts that in the presence of marked insulin resistance a 50% decrease in β -cell function would result in significant hyperglycemia. From this type of analysis it is predicted that tissue insensitivity to insulin will become a more important determinant of plasma glucose concentration as the loss of β -cell function becomes greater.

The observations in normal-weight and obese subjects cited previously, as well as the application of mathematical models, are consistent with observations in T2DM. Whereas a decrease in insulin sensitivity such as that induced by the development of adiposity will cause only a small change in glucose level in a person with a normal pancreas, in the patient with reduced islet function a much larger rise in glucose concentration will be observed (Fig. 21-16). This is due to the curvilinear relation between islet β -cell function and glucose.³⁴ As shown in Fig. 21-16, it requires more than a 75% loss of islet function for plasma glucose to rise above 126 mg/dL (7.0 mmol/L), but there is an increasingly greater glucose rise as islet function deteriorates further. Insulin resistance shifts the curve to the right, amplifying this effect. When tissue insulin sensitivity is improved by weight loss, again only small changes in fasting plasma glucose levels will be observed in sub-

FIGURE 21-16. Relationship of β -cell function to plasma glucose concentration and the impact of insulin resistance. The curvilinear relationship between β -cell function and fasting plasma glucose concentration dictates that in an individual with normal insulin sensitivity, the fasting glucose concentration will only reach the diagnostic level for T2DM (126 mg/dL; 7.0 mmol/L) when approximately 75% of β -cell function has been lost. When insulin resistance coexists in an individual with intact islet function and normal fasting plasma glucose, the compensatory enhancement in insulin output will prevent a marked change in plasma glucose concentration. Alternatively, in an individual with islet dysfunction sufficient to produce an elevation in the fasting glucose concentration, the additive effect of insulin resistance will produce a large increase in fasting glucose. A therapeutic intervention that reduces insulin resistance will reverse this change, resulting in a reduction in the glucose concentration.

jects with normal α - and β -cell function, but a marked lowering of the glucose concentration will occur in the hyperglycemic obese individual with impaired islet β -cell function. Taken together, these observations imply that a change in the degree of insulin sensitivity will have a greater effect on the fasting glucose level as islet function deteriorates.

FIGURE 21-15. Impact of insulin resistance on basal glucose regulation. The impairment of insulin action in the liver and insulin-sensitive peripheral tissues increases the glucose level, but as the islet compensates by increasing its insulin output and decreasing its glucagon release, hepatic glucose output and glucose disposal are modulated. The net effect is a small rise in glucose concentration and a large increase in insulin secretion. (Adapted with permission from Porte.⁹²)

A PATHOPHYSIOLOGIC MODEL OF T2DM

Figure 21-17A illustrates how the basal glucose concentration is regulated by a feedback loop in which the pancreatic islet acts as a glucose sensor to balance hepatic glucose delivery to the rate of insulin-dependent and insulin-independent glucose use. The occurrence of any change in glucose production by the liver or glucose use by the peripheral tissues is sensed by the islet and leads to changes in insulin and glucagon secretion to achieve a new steady state, which minimizes the overall change in glucose level. This new steady state returns the glucose concentration toward normal, but complete compensation cannot occur because this would result in the loss of the stimulus responsible for this adaptive change. The development of a β -cell lesion in T2DM would reduce plasma insulin levels. Because glucagon secretion is either wholly or partially regulated by the neighboring β -cell, an abnormal rise in α -cell release of glucagon would also occur (Fig. 21-17B). This reduction in insulin and increase in glucagon draining into the liver

FIGURE 21-17. Model for the development of hyperglycemia in T2DM. **A.** Normal basal glucose regulation. Insulin and glucagon, through their effects on the liver, fat, and muscle, modulate the plasma glucose level. Plasma glucose, by its direct interaction with the endocrine pancreas and by its modulation of the secretory response to nonglucose stimuli, feeds back to the islet to regulate insulin and glucagon output. **B.** Hypothetical initial islet lesion of T2DM. The impairment of islet function would be expected to reduce insulin and increase glucagon output, which would result in overproduction of glucose by the liver and underuse of glucose in the periphery, with a resultant increase in the glucose level. **C.** Hyperglycemia's effect to compensate for the islet lesion of T2DM. The increased glucose concentration that develops as a result of the deficient insulin and enhanced glucagon secretion in turn modulates the islet by increasing insulin secretion and decreasing glucagon release. As a result of these secretory changes, glucose production and use return toward normal but still remain elevated. **D.** Interaction of islet dysfunction and insulin resistance on basal glucose regulation in T2DM. The impairment of insulin action in the liver and peripheral tissues requires a marked additional increase in glucose concentration so that, in the presence of an impaired islet, a new steady state is achieved. Under these conditions, the islet may secrete "normal" or even "supranormal" quantities of insulin while secreting "normal" or "subnormal" amounts of glucagon, despite the presence of islet α - and β -cell dysfunction. The net result is a further increase in glucose production by the liver and glucose use by the peripheral tissues, until the renal threshold is exceeded when decompensation occurs. (Adapted with permission from Porte.⁹²)

would be expected to produce an increase in hepatic glucose production. Further, the reduced peripheral insulin level would impair glucose use by both fat and muscle, while glucose use in the non-insulin-dependent tissues proceeds normally. Due to the reduction in insulin secretion, insulin-mediated glucose uptake cannot increase sufficiently to compensate for the increased rate of hepatic glucose release, and the fasting glucose level tends to rise. This situation is only transient, because the elevation in the fasting plasma glucose level would lead to increased β -cell stimulation, thereby producing a more "normal" plasma insulin level, as depicted in Fig. 21-17C. In addition, the increase in glucose and insulin concentrations results in a reduction in glucagon secretion, but at the new steady state the glucagon level is not appropriately reduced for the degree of glycemia. Concurrent with these changes in islet hormone secretion, glucose production and use are moderated. However, at the new steady state, the rate of hepatic glucose

release will remain elevated and total glucose uptake will be increased due to the hyperglycemia. When hepatic and peripheral insulin resistance develops, the impairment of glucose uptake leads to a further increase in plasma glucose level. This additional hyperglycemia leads to further stimulation of the β cell with resultant normal or even supranormal insulin levels as well as further increase in hepatic glucose delivery and peripheral glucose uptake (Fig. 21-17D). Although a further reduction in the glucagon level occurs, the resultant level is still inappropriately elevated for the degree of hyperglycemia.

From this model it is apparent that islet dysfunction may be present regardless of whether basal insulin and glucagon levels are normal, high, or low in T2DM. Hyperglycemia is a compensatory mechanism that occurs in an attempt to overcome the islet secretory defect and insulin resistance. These adaptive changes result in a reregulated steady-state hyperglycemia, but complete compensa-

tion can occur only at glucose levels below the renal threshold. Once the renal threshold is exceeded, glycosuria occurs and the plasma glucose level cannot rise sufficiently to compensate for the islet defect. This then results in the development of a state of absolute insulin deficiency and glucagon excess with metabolic decompensation.

TREATMENT OF T2DM

At the present time, three major therapeutic modalities are used in type 2 diabetic subjects: diet, oral agents, and insulin administration. These interventions produce alterations in hepatic glucose production, insulin sensitivity, and/or insulin secretion and, as is apparent from the previously described closed feedback loop, any change in these variables should result in a reregulated steady state at a new level of glycemia.

Body weight reduction comprises two distinct phases: a period of weight loss, during which time there is a marked reduction in caloric intake, and weight maintenance at a new lower level, during which time more calories are being consumed, albeit less than the quantity taken prior to the initiation of weight loss. While a decline in glucose level occurs during both these phases, the mechanism by which glucose decreases is different. For an individual to lose weight, a reduction in caloric intake is required so that a state of negative caloric balance exists. Although it has been claimed that caloric restriction is associated with an improvement in insulin sensitivity, this does not occur during the period of weight loss. In fact, during periods of severe caloric restriction, the opposite is true and a state of insulin resistance exists.¹⁴⁹ Therefore, the initial decrease in fasting plasma glucose level that is observed during caloric restriction results from a reduction in hepatic glycogen stores with a resultant decline in glycogenolysis and a reduced rate of hepatic glucose release. As glycogen stores become progressively depleted, the liver tends to produce glucose predominantly by gluconeogenesis, with the rate of hepatic glucose production remaining low as the body attempts to maintain energy stores and minimize the loss of protein. Thus, after a period of fasting as short as 3 days, type 2 diabetes patients will demonstrate a significant reduction in their glucose levels, but these levels, while approximating those of healthy individuals, never reach the same low levels as normal subjects during a similar fast.¹⁵⁰ However, as soon as caloric intake increases, and weight maintenance is achieved, hepatic glycogen is replaced, glucose release is enhanced, and glucose levels tend to rise once again. Thus although improved insulin action is not a factor in the lowering of glucose levels during a hypocaloric diet, once body adiposity is reduced and weight is stabilized at a new lower level, any lowering of plasma glucose is due to improved hepatic and peripheral insulin sensitivity. The magnitude of the glucose level reduction will in large part be related to this enhancement of insulin sensitivity and is of most benefit to those individuals with poor islet function and marked hyperglycemia, in whom even a small improvement in insulin action can lower glucose concentrations (Fig. 21-16). This improvement in peripheral insulin sensitivity is largely due to an enhancement of postreceptor insulin action,¹⁵¹ with some increase in insulin receptor number also occurring.¹⁵² Some of these improvements in hepatic and peripheral glucose metabolism may also be the result of an increase in insulin secretion. Enhanced insulin release has been demonstrated in type 2 diabetes patients given an oral glucose challenge following weight reduction¹⁵¹⁻¹⁵³ and in a group of severely hyperglycemic

subjects in whom the plasma glucose level was halved to approximately 150 mg/dL (8.3 mmol/L) following 4-12 weeks of severe caloric restriction, with a resultant increase of about 65% in the insulin response to tolbutamide.¹⁵⁴

A number of oral agents are now available that are capable of stimulating insulin secretion (see Chap. 32). All these agents can effectively lower plasma glucose levels, but this effect is dependent on the presence of a responsive endocrine pancreas. Long-term administration of sulfonylureas is associated with reduced plasma glucose levels, but basal and stimulated insulin levels are often unchanged.^{155,156} This similarity of insulin levels is misleading, however, because when glucose is administered to match the glucose levels to those present prior to initiation of treatment, marked increases in basal and stimulated insulin levels are apparent.^{157,158} This observed increase in the slope of glucose potentiation suggests that sulfonylureas improve β -cell responsiveness to glucose.¹⁵⁸ Sulfonylureas are also capable of reducing basal hepatic glucose production, and this reduction has been maintained for periods of up to 18 months.^{98,99} The magnitude of this reduction appears to be a major determinant of the hypoglycemic effectiveness of these compounds. This decrease in the rate of hepatic glucose output is related to the change in basal insulin secretion. This relation between hepatic glucose release and basal insulin secretion, coupled with a marked enhancement of β -cell responsiveness to glucose, clearly links a major proportion of the decline in hepatic glucose production and the resultant glucose-lowering effect of these agents to the improved insulin secretion. Although it has been suggested that these compounds have a direct effect on hepatic sensitivity, the variability of findings preclude the drawing of a definite conclusion regarding this possibility. However, in many patients, sulfonylurea administration does appear to improve peripheral insulin sensitivity measured *in vivo*, resulting in an increase in insulin binding and an enhancement of postreceptor function, the latter being the predominant improvement.⁹⁹ This change in intracellular insulin action results in an increase of nearly 40% in the maximal response to insulin in some type 2 diabetics.⁹⁹ This ability of sulfonylureas to improve peripheral insulin sensitivity also appears to be a function of their capacity to enhance insulin secretion. This is suggested by the fact that type 1 diabetic subjects who are insulin resistant and incapable of enhancing their insulin output do not exhibit an improvement of insulin sensitivity when treated with these agents.¹⁵⁹ Therefore, we conclude that sulfonylureas result in a steady-state reregulation of plasma glucose at a lower level largely due to their direct and persistent effects on the pancreatic islet. More recently, two new classes of β -cell secretagogues have been developed and introduced into clinical practice. The first is the meglitinide repaglinide and the second the D-phenylalanine analogue nateglinide. As with the sulfonylureas, they appear to bind to the ATP-sensitive potassium channel.^{160,161} However, due to the fact that these newer classes of agents have a more rapid onset of action and a shorter half-life, they tend to have a greater effect on early postprandial insulin release compared to basal insulin, thereby being more efficient in suppressing meal-related hepatic glucose production.¹⁶²

The biguanide metformin has long been available for the treatment of type 2 diabetes. Its predominant effect appears to be on the liver, where it primarily reduces basal hepatic glucose production.¹⁶³ This effect may be mediated by an enhancement of the action of insulin in the liver or perhaps by an alteration in substrate flow, primarily from the splanchnic bed.¹⁶⁴ It has been postulated that a portion of the effect of this agent to improve glucose metab-

olism may also be mediated by an improvement in peripheral insulin sensitivity.¹⁶⁵ However, this effect does not appear to be consistent, although it is clear that the major beneficial effect is mediated through the liver.

Another recent addition to the classes of oral medications available for treating hyperglycemia are the PPAR- γ -agonist thiazolidinediones. These agents work primarily by enhancing insulin sensitivity in the peripheral insulin-sensitive tissues, namely, the muscle and adipose tissue, while having a much smaller effect on the liver.^{166,167} The mechanism by which enhancement of signaling via PPAR- γ improves glucose uptake has not been determined. It has been suggested that the effect of these agents to enhance insulin action may be mediated in part by a change in free fatty acid flux from the adipocyte.¹⁶⁸ In this context, it is also of interest that in small studies it has been demonstrated that administration of these compounds has been associated with a redistribution of central adiposity from the intra-abdominal to the subcutaneous fat depot.¹⁶⁹ It also appears that these agents may improve β -cell function as the relationship between insulin sensitivity and insulin levels is improved and disproportionate proinsulinemia is partially ameliorated.^{170,171} The recent suggestion that PPAR- γ receptors may be present on islets raises the interesting possibility that this effect of thiazolidinediones to improve β -cell function may be in part occurring via a direct effect on the β cell.¹⁷²

Exogenous insulin serves to substitute for the β -cell defect of type 2 diabetes, and if sufficient insulin is administered, normoglycemia can be achieved.^{138,139} This reduction in glucose level is a function of insulin's ability to suppress hepatic glucose release and enhance peripheral glucose uptake. Intensive insulin treatment is capable of reducing hepatic glucose production so that after only 3 weeks of therapy, the rate of glucose output approximates that observed in normal subjects.¹³⁹ Using this same treatment regimen, near normalization of fasting glucose levels is associated with a 74% improvement in the maximal glucose disposal rate without any improvement in adipocyte insulin binding.¹³⁹ This improvement in postreceptor function with insulin administration suggests that a reversible component of the postbinding abnormality is the result of hypoinsulinemia or some other metabolic factor, such as hyperglycemia. Improved glucose utilization has been demonstrated for periods of up to 2 weeks following withdrawal of insulin therapy.¹³⁹ Although this lower plasma glucose level may provide less stimulation to the β cell, resulting in reduced basal insulin secretion, it has been demonstrated that intensive glucose control may improve the insulin response to glucose and nonglucose stimuli.^{138,139,173} Although the first-phase insulin response to glucose, long considered a marker of T2DM, does not improve, the second-phase insulin response is enhanced. Furthermore, the improved glucose control results in a nearly threefold increase in the insulin response to glucagon¹³⁸ and an improvement in the C-peptide response to arginine.¹⁷³ However, once intensive insulin therapy is discontinued, the subsequent rise in glucose levels is again associated with steadily deteriorating β -cell function.¹⁷³ As noted, even though β -cell function may improve when glucose levels decline as a result of insulin treatment, islet stimulation is reduced, and usually the endocrine pancreas is suppressed. Therefore, the total insulin requirement will need to be met by exogenous insulin administration and the treatment program for an insulin-treated type 2 diabetic subject becomes very similar to the regimen of a type 1 diabetes patient. Thus the treatment program will require well-spaced meals and multiple doses of insulin. When complete replacement is required, the amount of insulin needed is not related

to the degree of hyperglycemia, but rather relates to body adiposity and other factors that determine insulin resistance. Thus in lean individuals a daily dose of 40–50 U may suffice, while in grossly obese subjects the requirement may be as great as 150–200 U/d.

GENETIC FACTORS IN T2DM

The advancement in our knowledge related to the pathogenesis of type 2 diabetes and the improved effectiveness of therapy that is based on this information have been matched in part by progress in our understanding and ability to identify genetic causes of disease. It now appears that type 2 diabetes is a polygenic disease that in most instances probably requires the interaction of at least two genetic factors: one related to β -cell dysfunction and one related to insulin resistance. In the process of searching for the genetic causes of type 2 diabetes, several rare forms of disordered glucose metabolism have been shown to be caused by gene defects involving the β cell and the insulin receptor.

Two groups of patients with type 2 diabetes and identified gene defects associated with β -cell dysfunction have been described. The first group consists of the maternally inherited mitochondrial syndromes with diabetes originally described as being associated with various neuromuscular disorders, but recently found to present at any age independently of or prior to neuromuscular disease with glucose intolerance or type 2 diabetes.^{174,175} The second group also presents as glucose intolerance or type 2 diabetes with a different inheritance pattern and has been called maturity-onset diabetes of the young (MODY) since it was first described clinically on the basis of its presentation under age 40 with a dominant inheritance pattern.^{36,176} For a comprehensive description see the reviews by Fajans and associates¹⁷⁷ and Kahn and Porte.¹⁷⁸

Similarly, molecular studies have found relatively rare defects associated with insulin resistance that are associated with T2DM and mutations in the insulin receptor gene.^{179–181} Two clinical features commonly observed in these syndromes are acanthosis nigricans and hyperandrogenism (in female patients). However, each set of defects is defined by the presence or absence of specific clinical features. One, called *type A insulin resistance*, is defined by the triad of insulin resistance, acanthosis nigricans, and hyperandrogenism in the absence of obesity or lipoatrophy.⁹³ Another consists of patients with the clinical diagnosis of *leprechaunism* with multiple abnormal features presenting during gestation or soon after birth, including intrauterine growth restriction and impaired glucose tolerance (IGT) with intermittent fasting hypoglycemia.^{182,183} These patients usually die within the first year of life. A third syndrome is the *Rabson-Mendenhall syndrome* that is associated with short stature, abnormalities of teeth and nails, and pineal hyperplasia.¹⁸⁴ For a comprehensive description see the review by Taylor.⁹³

These known β -cell and insulin receptor genetic syndromes and the high concordance of T2DM in identical twins compared with fraternal twins have stimulated a major search for predisposing gene defects in the more typical older-onset T2DM patients, but the likely heterogeneity of defects has made their identification difficult, and despite many promising associations between gene polymorphisms and hyperglycemia, there is no genetic defect that has yet been unequivocally identified to cause the disease more commonly affecting T2DM patients. Before describing in greater detail the known rarer causes of diabetes mentioned above, some discussion of the status of genetic studies on the more common form of type 2 diabetes is warranted.

Genetic Studies of T2DM

A variety of metabolic studies have demonstrated impaired β -cell function and insulin resistance in family members of subjects with type 2 diabetes^{185,186} and in identical twins of type 2 diabetic patients with normal glucose tolerance who have a high likelihood of developing the syndrome.¹⁸⁷ It is still not clear in any individual patient which of these two disorders began first, how much is related to the environment and to genetic dysfunction, and how much of the full-blown syndrome is secondary to the hyperglycemia. There is evidence that both β -cell function^{188,189} and insulin sensitivity¹⁹⁰ are familial traits in certain populations, and abnormalities of insulin secretion and sensitivity have been reported to predate the onset of glucose intolerance.^{185,186} Nevertheless, there remain many uncertainties regarding progression from normal to impaired glucose tolerance and eventually to fasting hyperglycemia and clinical T2DM. For this reason it has been difficult to identify the genetic defects that are presumed to underlie much of the risk of T2DM. The most convincing evidence of a genetic factor is derived from twin studies.^{191–195} Although there is some variation in reported risk when comparing monozygotic and dizygotic twins, concordance is always higher for monozygotic twins than dizygotic twins. Initial studies reported almost 100% concordance in monozygotic twins and roughly 50% in dizygotic twins, but ascertainment bias was believed to be a serious problem in the generation of these data. More recent studies suggest that concordance is more likely to be in the 60–70% range in monozygotic twins and roughly 10–20% in dizygotic twins. Thus the relative risk of development of T2DM in the sibling of an identical twin with the disease was increased 2- to 3.4-fold compared with nonidentical twins, and this increases with age. Further evidence for genetic factors is the familial aggregation of type 2 diabetes in a variety of ethnic groups, and a variation of prevalence among these groups, ranging from as high as 80% in subjects such as the Pima Indians whose parents both had early onset diabetes to the estimates of approximately 5% in Caucasian Americans, 10% in African Americans, 25% in Mexican Americans, and 35% in Pima Indians overall.¹⁹⁶

Positional cloning has been attempted after locating susceptibility genes from either a genome scan using random markers or discrete regions of a chromosome which are strongly associated with the rare genetic forms of the disease, or one of the physiological markers believed to contribute to the etiology of the disease. The generally disappointing results have now led to the common belief that T2DM is a polygenic disorder which probably results from several combined gene defects that interact with environmental factors to produce the eventual clinical syndrome. This being the case, it is perhaps not surprising that none of these genetic approaches has been particularly successful so far in unraveling the important, underlying etiological factors in late-onset T2DM. Nevertheless, success using the MODY phenotype has encouraged continuing efforts using more powerful techniques. To date, the study of candidate genes has been by far the most commonly used approach. However, a high degree of heterozygosity is required to optimize sib-pair analysis, and identification of affected subjects is arbitrary, being based on a continuous physiological variable. Identity by descent or identity by state can be utilized, but considering the age of onset of T2DM, identity by state is by far the most frequent method. Unfortunately, this requires determination of the frequency of the alleles in an appropriately matched population and may require a large number of pairs. Until recently, candidate

genes have usually been evaluated in populations of unrelated individuals. Avoiding errors in conclusions in these studies requires careful clinical and metabolic phenotyping using well-matched case and control populations, with particular regard to avoiding differences in ethnicity and genetic background. Since many genes have now been cloned and sequenced using molecular scanning methods designed to detect changes in nucleotide sequence in fragments of DNA, such as single-strand confirmation polymorphism (SSCP) or heteroduplex analysis, it is possible to test a very large number of potential associations. While an association between a mutation or polymorphism with β -cell dysfunction, insulin resistance, impaired glucose tolerance, or diabetes can then be analyzed, care must be taken to confirm positive findings using some other method to eliminate a chance occurrence or an unknown difference in the background of the affected and control subjects.

Candidate Genes for T2DM

Glucokinase

All of the known MODY genes have been considered as possible candidates for gene defects in late-onset T2DM. Positive associations between T2DM and particular glucokinase polymorphisms were originally observed in American Blacks and Mauritian Creoles,¹⁹⁷ suggesting that the glucokinase locus might be implicated in diabetes in these populations. However, mutations in the coding region were not found. Variants were observed in the liver promoter at –258 and the islet β -cell promoter at –30. A block transversion mutation near this latter region in the rat promoter resulted in a 22% reduction in promoter activity *in vitro*,¹⁹⁸ and the region of the –30 base is known to be completely homologous between the rat and the human. However, the functional importance of this region in humans is not known for certain. This variant promoter was associated with an increased frequency of impaired glucose tolerance in a group of Japanese middle-aged men who were surveyed in a population under study in Seattle, and when this population was resurveyed 5 years later, this was confirmed.¹⁹⁹ Further analysis of the population demonstrated an association between this variant and a 30% reduction in early insulin responses to oral glucose challenge. This was true whether or not the individual had normal or impaired glucose tolerance. Thus it was concluded that the –30 promoter variant may be an example of a common genetic variation which increases the risk of impaired glucose tolerance and contributes to the increased frequency of T2DM in this population. However, the pathophysiology of impaired glucose tolerance is heterogeneous even in this population, and therefore multiple factors are probably interacting to produce clinical hyperglycemia. Furthermore, as discussed earlier, for this phenotyping it is necessary to recognize that insulin sensitivity modulates β -cell responses to glucose, and therefore the assessment of β -cell function can be complex. This may explain why populations do not show linkage between the glucokinase locus when clinical diabetes is used as the phenotype,^{188,200–203} but may show association with glucose intolerance.^{199,204}

The High-Affinity β -Cell Sulfonylurea Receptor (SUR-1)

This molecule couples with an inwardly rectifying potassium channel (Kir6.2) and acts as a regulatory subunit for coupling glucose metabolism through its nucleotide binding sites for ATP and ADP to regulate the potassium channel and membrane conduc-

tance for control of calcium influx and insulin secretion.²⁰⁵ A number of variants of this receptor have been described.

A silent variant in exon 22, ACC → ACT at nucleotide 761 was more common in patients than in controls with an odds ratio of 3, while an intronic T → C change at position -3 of the exon 24 splice acceptor site was also more common, with an odds ratio of 1.9. The combination occurred in 8.9% of patients and 0.5% of control subjects. Therefore, it was suggested that this locus may be a contributor to T2DM in Northern European Caucasians.²⁰⁶

Sixty-three T2DM patients were completely screened from a Danish population.²⁰⁷ One variant, a C/T in the silent exon 18 at position 775 and an intron 3c/-3t were found together more frequently in T2DM patients than control subjects. Ten of 300 unrelated, healthy, young Danish Caucasians had the combined at-risk genotype associated with a 50% reduction in serum C peptide and a 40% reduction in serum insulin responses to tolbutamide, but not to glucose injection. Therefore, there is only a possible association with T2DM and SUR-1 in some populations.

GLUT-2

GLUT-2 is a high- K_m (low affinity) glucose transporter expressed in liver, islet β cells, kidney, and intestine. Coupled with glucokinase, GLUT-2 has been proposed to act as part of the glucose-sensing mechanism in β cells.²⁰⁸ A sib-pair analysis in Pima Indians demonstrated significant linkage between GLUT-2 and the acute insulin response to glucose, but no linkage with T2DM.¹⁸⁸ Studies in a Japanese group of pedigrees with affected members showed a possible association between a polymorphic marker near the GLUT-2 locus, but follow-up in 60 subjects with complete gene scans found three Thr110Ile mutations and one Pro68Leu mutation that were not associated with disease.²⁰⁹ In summary, association with disease has not been found.

Glucagon Receptor

A screening study of the glucagon receptor gene was reported in 1995 in a population of Sardinian and French families.²¹⁰ Eighty multiplex, French type 2 diabetic families were investigated first. In exon 2 a single heterozygous missense mutation GGT 40 → AGT 40 (Gly40Ser) was identified in 5 of the 80 tested. Subsequently, a further 136 unrelated patients from additional families and 96 unrelated patients from Sardinia were screened. The overall frequency was 4.6% in the French and 8.3% in the Sardinians. Three control groups were also tested. The trend of the two populations was similar. When tested together, there was a highly significant association with T2DM. Linkage was tested using the transmission/disequilibrium (TD) test and the estimated transmission frequency of .727 was significantly higher than the expected value of .5. This required subjects with impaired glucose tolerance, impaired fasting glucose, or T2DM to be considered affected, although impaired glucose tolerance and impaired fasting glucose combined were also significant. Overt T2DM assessed alone was not. This receptor variant was expressed in BHK cells and transfected clones tested for binding. Compared to wild-type receptor, labeled glucagon had a threefold lower affinity for the mutant.

Unfortunately, subsequent studies were quite variable and not confirmatory.²¹¹⁻²¹⁹ Similar association data have been reported with the -30 β -cell glucokinase promoter (see above), and suggest the possibility that there may be genetic factors which predispose to impaired glucose tolerance, but whose impact on blood glucose is so modest that because they are common variants, the effect does not become noticeable when surveying the entire population and

comparing overt diabetes as the affected with a group including impaired glucose tolerance and impaired fasting glucose among the nonaffected populations. Thus detailed phenotypic characterization may be critical if such a variation is a significant contributor to the eventual development of risk for T2DM in a population.

Other Candidate Genes

Many other candidate genes have been screened, but none has been consistently associated with type 2 diabetes. Total genome scans have been almost as equally disappointing to date, although not nearly as extensive.²²⁰⁻²²⁴

Genome-Wide Scanning for Type 2 Diabetes

There are five groups that have assembled the necessary resources, including identification of a suitable population, clinical phenotyping, metabolic studies, and genetic analytic techniques, that are enabling them to pursue this approach. However, since the populations vary and the selection criteria are different, it is likely that the outcomes will be different.

The first group reported on a population of 217 individuals from 26 families screened from 4000 individuals in a population isolated in western Finland (Botnia), an area where Swedes are living.²²⁰ The total population of the region is 60,000. Over a 5-year period, families with a positive history of diabetes at four health centers were recruited to participate in clinical characterization studies with an overall participation rate of 90%. In total, 1180 type 2 diabetes patients and 3005 family members were phenotyped. Families containing three or more affected individuals, with at least one subject having disease onset before age 60 years and another before age 65 years, were selected for analysis. A 10-cM sequence length polymorphic map was made of the 217 individuals and a nonparametric method used for evaluation. This analysis revealed no significant or even suggestive evidence for susceptibility loci predisposing to T2DM. However, to further phenotype individuals, they selected the early insulin response during the oral glucose tolerance test (30-minute insulin level) among affected individuals as an indicator of insulin secretion to rank families. Families were partitioned into four quartiles and the data reanalyzed. In the quartile with the lowest insulin levels, a region near D12S366 on chromosome 12q was highly significant, and with additional markers in this region, evidence for linkage was observed with an approximate LOD score of 3.65. This is the region of the *MODY-3* gene, but the lowest quartile families do not fit the usual phenotypic definition of *MODY-3* families. Subsequent screening of 86 of these subjects failed to demonstrate a mutation in the *HNF1 α* gene, suggesting that a nearby gene is possibly involved.

Hanis and colleagues performed a sib-pair analysis on a group of Mexican American families from Starr County, Texas.²²⁵ This group consisted of 408 Mexican American individuals with 330 affected sib-pairs from 170 sibships. One marker at D2S125 showed evidence for linkage with an LOD score >2.6. Follow-up studies were made in another group of Mexican-Americans consisting of 166 individuals from 76 sibships for a total of 110 affected sib-pairs, and were compared with a group of Japanese affected sib-pairs consisting of 213 individuals from 97 sibships for a total of 140 affected sib-pairs. An oral glucose tolerance test using WHO criteria, current oral hypoglycemic agent, or insulin use was used to determine the affected. Several markers showed some evidence for linkage with type 2 diabetes in this second sample. When combined, only D2S125 met the genome-wide criteria with significant

evidence for linkage with IBS X₂ and MLS values in the combined sample of 30.25 and 4.10. There was no evidence for linkage in the Japanese population or in a group of heterogeneous non-Hispanic whites who were also screened. Subsequently, positional cloning at this location on chromosome 2 demonstrated a common (G/A) variation in an intron of the gene encoding calpain-10.²²⁶ A homozygous polymorphism (G/G) of UCSNP-43 was the at-risk genotype in this Mexican-American population. Recently, three biallelic polymorphisms UCSNP-43 (G/A), -19 (32 bp ins/del), and -63 (C/T) have been found to have the greatest association with T2DM in this population.²²⁷ In Pima Indians this genotype was not associated with type 2 diabetes, but in normal glucose-tolerant relatives, GG homozygotes were found to be relatively insulin resistant and to have reduced calpain-10 mRNA expression in skeletal muscle.²²⁸ A northern European population from Botnia, Finland was also tested and the G/G polymorphism was again associated with T2DM.²²⁶ Therefore, it appears to be a risk factor in some populations despite being in a noncoding region of the gene without any clear-cut function. The message is expressed in many tissues and therefore its physiologic impact is not yet known.

In summary, whole genome searches using the affected sib-pair method have been undertaken by a variety of groups to complement the ongoing work on candidate genes for T2DM. The results to date have been modest, largely because of the difficulties of the effort. The FUSION group has pointed out that 400 pairs typed on a 10-cM map will require a 1.8-fold excess risk to siblings of affected individuals at an LOD score of 3.0 with 82% power. However, this drops to an LOD score of 1.0 for a 1.4-fold excess risk. It is also pointed out that it would require 800 such pairs to have 70% power to detect a locus with an impact estimated by the Starr County investigators for their chromosome 2 finding to produce an LOD score of 3.0, and even this would be reduced to an LOD score of 1.59 if the locus only confers a 1.2-fold excess risk. Thus it is becoming obvious that detection of genes for type 2 diabetes is going to be extremely complex and difficult if the impact of these genes is relatively modest and their frequencies either relatively low or very high or if they interact in some way, which is likely. This probably explains why even the results of the initial efforts have not replicated one another, and only one potential gene has been identified. Thus identification of genes for type 2 diabetes will almost certainly require pooling of data among investigative groups. Fortunately, such efforts have begun, and with the recent success of the human, mouse, and rat genome sequencing efforts, should lead to rapid progress.

GENETIC STUDIES OF RARER FORMS OF ALTERED GLUCOSE METABOLISM ASSOCIATED WITH DEFECTS IN β -CELL GENES

Mitochondrial Diabetes

The first case of mitochondrial disease with diabetes without muscle or nerve dysfunction except for sensorineural hearing loss was reported a decade ago,¹⁷⁴ with an increasing number of cases seen since. The general characteristic appears to be an early, selective impairment of insulin secretion and a later global metabolic dysfunction similar to classical T2DM with insulin resistance and fasting hyperglycemia.²²⁹⁻²³¹ However, the diabetes often progresses to absolute insulin deficiency and the need for insulin treatment. In some cases an autoantibody to glutamic acid decarboxylase (GAD)²³² or islet cells (ICAs)²³³ is present. Since these markers are

used to assist in the diagnosis of T1DM, there can be confusion regarding classification. In a detailed analysis of subjects with a known mitochondrial defect from families with associated diabetes, those with normal glucose tolerance or impaired glucose tolerance appear to have either a failure to prime the insulin secretory response by a prolonged glucose infusion or an inability to stimulate ultradian insulin secretory-oscillations.^{231,233} As the disease progresses, clear-cut impaired insulin secretion in response to a standard glycemic challenge becomes obvious, and insulin resistance may develop.^{175,234} Since it has been shown that islet β cells are dependent on mitochondrial metabolism for function,^{235,236} with associated high rates of blood flow to the organ and relatively high rates of oxygen consumption, it is assumed that islets are a critical tissue, along with nerve and muscle, that depend on mitochondrial oxidative phosphorylation. Despite the general similarities that have been described, there are great differences among individuals in clinical presentation, age of onset, rate of progression, and eventual dependence on insulin. Furthermore, individuals with the same molecular lesion may have vastly different clinical manifestations, and/or several quite different clinical syndromes may have the same underlying genetic defect. Some of the heterogeneity can be explained by the tissue variability or cellular heterogeneity (i.e., heteroplasmic) nature of the mitochondrial basis for the disease and some by varying genetic backgrounds of the subjects. However, from the studies that have been performed it is clear that there is not always a correlation between molecular and clinical findings.

Maternally Inherited Diabetes and Deafness (MIDD)

The first single large pedigree with MIDD associated with a 10.4-kb deletion of mitochondrial DNA was described in 1992 by Ballinger and associates.¹⁷⁴ Further studies of this pedigree have shown the presence of a variety of mitochondrial rearrangements, and it is likely that the primary defect is mitochondrial DNA duplication.²³⁰ Shortly afterward, van den Ouweland and colleagues described a pedigree with maternally inherited diabetes and deafness with a heteroplasmic A $\rightarrow$ G mutation at 3243 in the tRNA^{leu(UUR)} portion of the mitochondrial genome.²³⁷ This was rather surprising since the same mutation had been previously reported to be associated with the MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes).²³⁸ The reasons why the phenotype varies are unknown, but may be because of differences in the degree of heteroplasmy. The clinical diagnosis of diabetes usually, but not always, precedes the detection of clinical sensorineural hearing loss, but the age of presentation in a rather large Japanese population has varied from 11 to 68 years.²³⁹ The identical clinical picture has also been associated with several other less common mitochondrial mutations. The most common of these, the tRNA^(lys) 8296 A $\rightarrow$ G mutation, was estimated to explain 1% of Japanese T2DM cases,²⁴⁰ and the 3271 T $\rightarrow$ C tRNA^{leu(UUR)} mutation to explain one-tenth as many.²⁴¹ An explanation for the poor correlation between the degree of heteroplasmy in peripheral tissues and the severity of the diabetes mellitus suggests that other genes or environmental factors are probably important to the clinical picture.

Other Mitochondrial Syndromes

Several neuromuscular mitochondrial syndromes are also associated with diabetes. The most common one is the MELAS syndrome, and it is usually also associated with the same 3243 A $\rightarrow$ G

mutation that can lead to MIDD. The explanation for the variation is not known, but presumably it results from heteroplasmy which can result in a variable phenotype, or from the interaction with other unknown genetic defects or polymorphisms. Furthermore, other mutations^{238,241} have been reported to be associated with this syndrome. Another rare mitochondrial syndrome is the Kearns-Sayre syndrome (KS syndrome), which is usually associated with a mitochondrial DNA deletion on muscle biopsy and is frequently associated with diabetes mellitus.^{229,242}

Maturity-Onset Diabetes of the Young (MODY)

In the great majority of patients with T2DM, a diagnosis is made in middle age. However, a subclass of this syndrome includes families in whom diabetes can be recognized in children, adolescents, and young adults, and has been clinically termed MODY.¹⁷⁶ Autosomal dominant inheritance has been established in these families, and at least five specific mutations have been described. However, this does not include all of the families in whom a dominant genetic pattern with young family members has been observed, so more mutations are yet to be discovered. At times these patients have been confused with T1DM patients because they are young, some variants lead to relatively severe forms of insulin-deficient diabetes, and by and large most patients with this syndrome are lean. However, most of the patients are ketosis resistant, and even those who need insulin for control of glycemia are not usually ketosis prone. Since the more common variety of T2DM can also be present among these families, it is possible for an individual family member to have both syndromes, and therefore relative insulin deficiency may become more evident in the presence of insulin resistance and obesity and during periods of stress, infection or trauma. In some MODY patients, there may be easily diagnosable clinical hyperglycemia, but in other members of the family with the same mutation, much milder degrees of hyperglycemia or glucose intolerance may be present. In the younger members diagnosed by genetic screening, some may have normal glucose tolerance although, when studied carefully, subtle abnormalities of insulin secretion may be detectable. MODY can be suspected and recognized if T2DM occurs in three or more generations and the pattern of inheritance conforms to an autosomal dominant type. Families have been diagnosed in Europe and the United States, as well as Japan and other Asian countries. Progression of hyperglycemia depends on the specific genetic defect. Glucose tolerance may fluctuate depending on other factors, and variability among family members is assumed to be related to other genetic and environmental factors that can fluctuate over time. The true prevalence of MODY is unknown, but estimates have varied from 2–5% of patients with T2DM to 10–20% of families with T2DM in multiple family members. Studies of the insulin secretory defects early in the course of the disease can distinguish among the various genetic mutations.

MODY-1 (Hepatocyte Nuclear Factor-4 α [HNF-4 α])

In 1996, mutations in the HNF-4 α gene were shown to be the cause of MODY-1.²⁴³ In this early large pedigree, there was a C $\rightarrow$ T substitution in codon 130 leading to a threonine-to-isoleucine substitution and a C $\rightarrow$ T substitution in codon 268 which generated a nonsense mutation CAG (Gln) $\rightarrow$ TAG (AM) (Q268X). Both the isoleucine 130 and the amber mutation at codon 268 were present on the same allele.²⁴³

There are some affected subjects that have normal glucose tolerance and some that have impaired glucose tolerance, but most have clinical hyperglycemia, although the age of diabetes onset is variable.²⁴⁴ Study of marker-positive family members with normal or slightly impaired fasting glucose shows reduced insulin secretory rates above 7 mmol/L glucose at steady state and an impaired ability to prime β -cell function after a 42-hour intravenous glucose infusion (Fig. 21-18).^{244,245} This pattern is different from MODY-2 and MODY-3. Approximately one-third of affected individuals will require insulin treatment, and patients with this form of diabetes may have microvascular complications. Homozygous loss of functional protein in mice leads to embryonic lethality and defects in gastrulation.²⁴⁶ However, there are no obvious hepatic, renal, or gastrointestinal defects in family members.

Several other families in the UK, Japan, and Scandinavia have been reported (Fig. 21-19), but this mutation is still a relatively infrequent cause of MODY. By 2001 only 13 families had been identified.¹⁷⁷

MODY-2 (Glucokinase)

The first candidate gene linkage in the MODY syndrome was described from a study of 16 French families with three or more generations of IGT or type 2 diabetes, and was found to link to a polymorphic marker adjacent to glucokinase at chromosomal

FIGURE 21-18. Insulin secretion rates during graded intravenous glucose infusions administered to 6 marker-negative and 10 marker-positive subjects from the R-W MODY-1 family after an overnight fast (**baseline**) and after a 42-hour intravenous infusion of glucose (**postglucose**) at a rate of 4–6 mg $\cdot$ kg⁻¹ $\cdot$ minute⁻¹. Data expressed as means $\pm$ SE. (Reproduced with permission from Froguel et al.^{244,245})

FIGURE 21-19. The distribution of HNF-4 α gene mutations in MODY-1 families. When there is more than one family with a mutation, the number of families is shown in parentheses. (Reproduced with permission from Hattersley.²⁶¹)

locus 7p.²⁴⁷ By 2001, a large number of families with more than 130 different mutations involving all 10 exons, in populations distributed worldwide of all racial types (Caucasian, black, and Asian) were described (Fig. 21-20).^{177,244} Twenty-eight of these mutations alter the protein sequence by changing one amino acid; six transform the sequence at the site of RNA splicing of an intron-exon or exon-intron junction, resulting in the expression of an abnormal species of messenger RNA; and eight are responsible for the synthesis of a truncated protein by creating a premature termination codon by point mutation or deletion. Most are only present in single families.

Glucokinase is present at critical levels in the liver and the pancreas, playing an important role in hepatic glucose storage by phosphorylation of glucose after absorption and in the endocrine pancreas by coupling the first step of glucose metabolism to insulin secretion through the generation of ATP and regulation of β -cell potassium conductance and calcium levels.²⁴⁸ The degree of hyperglycemia is relatively mild, although it can be usually detected in children. Long-term complications are relatively unusual with this form of diabetes. Hyperglycemia remains stable for many years whether treated or not and progresses very little, in contrast to typical T2DM. Treatment with oral agents is usually satisfactory, and can lead to reasonable control for many years (Fig. 21-21).^{176,244,249,250}

The major functional defect that has been observed is impaired insulin secretion; however, this may not be evident unless sophisticated testing is performed. Twenty-four-hour profiles of affected subjects show persistent, round-the-clock hyperglycemia, but insulin levels are only slightly reduced after meals and are no different at baseline and between meals. However, when glucose levels are matched during continuous infusions, they are reduced by at least 50%. As glycemia is increased, they are markedly reduced compared to healthy controls (Fig. 21-22).²⁵⁰⁻²⁵² Islet priming by a 42-hour glucose infusion shows a response, but one of smaller magnitude than controls, and it is quite different from that observed in MODY-1 or MODY-3.^{244,245,253} After an overnight fast, the entire curve is shifted down and to the right, whereas in MODY-1 the curve rises normally until approximately 8 mmol/L and is then essentially flat throughout as it is in MODY-3. In MODY-2, glucose potentiation of arginine-induced insulin secretion is reduced, and glucose suppression of arginine-induced glucagon secretion is impaired.²⁵⁴ The average fasting hepatic glycogen content has been shown to be similar in glucokinase-deficient and control subjects, but it is increased in both groups after meals, following a normal pattern throughout the day. However, the net increment in hepatic glycogen content after each meal was 30–60% lower in glucokinase-deficient subjects.²⁵⁵ Occasional cases of late-onset T2DM have been reported with muta-

FIGURE 21-20. The exon-intron organization of the human glucokinase gene and mutations found in subjects with MODY-2. Amino acid residues are numbered as in the β -cell form of human glucokinase. The two amino acid polymorphisms in the unique NH₂-terminal portion of β -cell glucokinase that is encoded by exon 1a are indicated (Asn/Gln-4 [D/N4] and Ala/Thr-11). (Reproduced with permission from Froguel et al.²⁴⁴)

FIGURE 21-21. The relationship between age and fasting plasma glucose values in MODY-2 patients with glucokinase mutations. The fasting plasma glucose values increase very gradually with age ($r = 0.41$; $p = 0.002$). (Reproduced with permission from Tanizawa, Y, Chiu KC: Role of glucokinase in the defective insulin secretion of diabetes. In: Flatt PR, Lenzen S, eds. Insulin Secretion and Pancreatic β -Cell Research. Smith-Gordon; 1994: 437.)

tions in glucokinase,²⁵⁶ and the pattern of inheritance could not be differentiated from that of MODY. It is likely that some mutations produce a syndrome so mild that only obesity in middle age or aging-associated insulin resistance is associated with clinical hyperglycemia.

FIGURE 21-22. Insulin secretion rates during graded intravenous glucose infusions administered to six MODY-2 subjects with glucokinase (GCK) mutations and six control subjects after an overnight fast (BASELINE) and a 42-hour intravenous infusion of glucose (POSTGLUCOSE) at a rate of $4-6 \text{ mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. Administration of the glucose infusion enhanced the insulin secretory response to glucose in both control and glucokinase-deficient subjects. Data are expressed as means $\pm$ SE. (Reproduced with permission from Froguel et al.²⁴⁴)

MODY-3 (Hepatocyte Nuclear Factor-1 α [HNF-1 α])

In 1995, a genome-wide segregation analysis of highly informative microsatellite markers in 12 French families with MODY reported the localization of a gene to the long arm of chromosome 12 in 6 of 12 families.²⁵⁷ In 1996, Yamagata and associates showed that MODY-3 was the gene encoding HNF-1 α , a transcription factor involved in tissue-specific regulation of liver genes which is also expressed in pancreatic islets and other tissues.²⁴³ Seven different mutations in HNF-1 α were found to cosegregate with MODY-3 diabetes. More than 120 different mutations have now been identified in MODY-3 families of various populations (Fig. 21-23).^{243,258-261} HNF-4 α is a transcription factor for HNF-1 α . There is a mutation in one family with MODY-3 diabetes in the conserved region of the promoter that disrupts the binding site for the transcription factor HNF-4 α .²⁶² This finding suggests that a 50% reduction in HNF-1 α activity can lead to β -cell dysfunction and hyperglycemia. The true frequency of genetic variation in HNF-1 α remains to be determined.

An insulin secretory defect in the absence of insulin resistance was observed in diabetic and nondiabetic carriers of MODY-3 mutations with a pattern that during sequential glucose infusions is distinct from MODY-1 and MODY-2.^{244,253} In marker-positive normal glucose tolerance (NGT) subjects, the defect was not observed at glucose levels lower than 8 mmol/L, but became evident as glucose rose above this level (Fig. 21-24). Priming was still present in nondiabetic marker-positive subjects, but not in those with clinical hyperglycemia (Fig. 21-25). This type of MODY resembles late-onset type 2 diabetes in its natural history, with patients progressing rapidly from impaired glucose tolerance to overt hyperglycemia with severe deterioration of insulin secretion. Thus it is frequently treated with oral hypoglycemic agents for a time, but often later requires insulin therapy.²⁶³ Complications, such as proliferative retinopathy, have been observed frequently and at rates comparable to those seen in late-onset type 2 diabetics. However, there is a low prevalence of obesity, dyslipidemia, and arterial hypertension, and unlike MODY-2, clinical disease with hyperglycemia usually develops after puberty.²⁶³

MODY-4 (Insulin Promoter Factor-1 [IPF-1])

One family with a mutation in the IPF-1 gene has been reported.²⁶⁴ IPF-1, also known as IDX-1, STF-1, and PDX-1, regulates both early pancreatic development and the expression of key

FIGURE 21-23. The distribution of HNF-1 α gene mutations in MODY-3 diabetes. When there is more than one family with a mutation, the number of families is shown in parentheses. (Reproduced with permission from Hattersley.²⁶¹)

endocrine β -cell-specific genes, most notably insulin. Targeted homozygous destruction in mice results in pancreatic agenesis.²⁶⁵ Family studies simulated by a case with homozygous mutations in exon 1 of the coding sequence with pancreatic agenesis and neonatal diabetes²⁶⁶ found a high prevalence of diabetes mellitus with age-dependent autosomal dominant transmission in six generations.²⁶⁴ The average age of onset of hyperglycemia is 35 years (range, 17–67 years) with the hyperglycemia clinically resembling MODY diabetes in that it is mild and treated with diet or oral hypoglycemic agents. The association between the mutation and the clinical syndrome was so significantly strong that the authors suggested the term MODY-4. Further screening in type 2 diabetic families in the UK uncovered several mutations associated with reduced function *in vitro* and an increased risk of

impaired glucose tolerance or type 2 diabetes, but not MODY. It thus appears that these mutations are risk factors for type 2 diabetes.^{267,268}

MODY-5 (Hepatocyte Nuclear Factor-1 β [HNF-1 β])

HNF-1 β is a member of a complex transcriptional regulatory network that includes HNF-1 α and HNF-4 α . It is a homeodomain-containing factor that is structurally related to HNF-1 α , and functions as a homodimer or a heterodimer with HNF-1 α . Fifty-seven unrelated Japanese subjects with MODY were screened for mutations in these genes, and one family with a nonsense mutation in codon 177 (R177X) of HNF-1 β was found, which in this family was associated with diabetes.²⁶⁹ This family is complex in that one parent has what appears to be late-onset T2DM with no mutations identified. Further screening has been reported in additional families with early-onset T2DM and a frameshift mutation with a GG insert in exon 3 of HNF- β for Ala 263 designated A263fsinsGG has been found.²⁷⁰ This MODY family has diabetes in three generations with renal dysfunction consisting of renal cysts, proteinuria, and/or elevated creatinine. Additional families screened for MODY or renal disease in the UK uncovered additional mutations segregating with hyperglycemia and renal disease.^{267,271–273}

More MODY mutants presumably will be found as only 60% of clinically dominant families with T2DM had an identified defect in 2001.

GENETIC STUDIES OF RARER FORMS OF ALTERED GLUCOSE METABOLISM ASSOCIATED WITH MUTATIONS IN THE INSULIN RECEPTOR GENE

Although insulin resistance plays a key role in the pathogenesis of type 2 diabetes, the molecular mechanisms that cause insulin resistance have not been elucidated in the majority of patients. However, there has been considerable success in identifying the cause of diabetes in several uncommon syndromes of insulin resistance due to mutations in the insulin receptor gene (see review by Taylor⁹³).

FIGURE 21-24. Relationship between average plasma glucose concentrations and insulin secretion rates during the stepped glucose infusion studies in seven diabetic MODY-3 subjects ($\square$), six nondiabetic MODY-3 subjects ($\blacktriangle$), and six control subjects ($\circ$). The lowest glucose levels and insulin secretion rates were measured under basal conditions, and subsequent levels were obtained during glucose infusion rates of 1, 2, 3, 4, 6 and 8 $\text{mg} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$. (Reproduced with permission from Byrne et al.²⁵³)

FIGURE 21-25. Clinical Syndromes

Leprechaunism

Leprechaunism is the most severe clinical syndrome caused by mutations in the insulin receptor gene.^{179–181,274} These patients have glucose intolerance despite having extremely high insulin levels (100-fold above the normal range). In addition to insulin

resistance, patients have multiple abnormalities (e.g., intrauterine growth restriction and fasting hypoglycemia) and usually die within the first year of life. These patients have inactivating mutations in both alleles of the insulin receptor gene. In inbred pedigrees, the patients are usually homozygous for a single mutant allele.^{274,275} In the absence of consanguinity, they are usually compound heterozygotes with two different mutant alleles.^{276,277}

Type A Insulin Resistance

Type A insulin resistance is defined by the triad of insulin resistance, acanthosis nigricans, and hyperandrogenism (in female patients) in the absence of obesity or lipodystrophy.^{93,181,278} Acanthosis nigricans and hyperandrogenism correlate with hyperinsulinemia, and it is believed that they are caused by “toxic” effects of insulin upon the skin and the ovaries, respectively.²⁷⁹ Because these patients have defects in the function of their insulin receptors, it is unlikely that the toxic effects of insulin are mediated by insulin receptors, but more likely by receptors for homologous peptides such as insulin-like growth factor 1.

Most patients with type A insulin resistance are heterozygous for a single mutant allele, most often a mutation in the tyrosine kinase domain of the receptor.^{93,180,181,280,281} Although some heterozygotes have abnormal glucose tolerance, most do not exhibit fasting hyperglycemia. These patients are usually less insulin resistant than patients with two mutant alleles. Patients with type A insulin resistance with two mutant alleles of the insulin receptor gene can develop overt diabetes with fasting hyperglycemia during childhood or adolescence, but usually do not have fasting hyperglycemia as infants.^{93,180,181,274,282,283}

Rabson-Mendenhall Syndrome

The Rabson-Mendenhall syndrome is defined by the presence of several clinical features, including extreme insulin resistance, acanthosis nigricans, short stature due to growth retardation, abnormalities of teeth and nails, and pineal hyperplasia.^{179–181,184} This syndrome is intermediate in clinical severity between leprechaunism and type A insulin resistance. Although the distinction between leprechaunism and the Rabson-Mendenhall syndrome may not be clear at the time of birth, it has been suggested that diagnosis of Rabson-Mendenhall syndrome only be made in patients who survive beyond 2 years of age. As in leprechaunism, patients with the Rabson-Mendenhall syndrome have inactivating mutations in both alleles of the insulin receptor gene.^{274,284,285}

Specific Mutations

Many different mutations have been identified in the insulin receptor. However, there are insufficient data to provide a reliable estimate of the prevalence of mutations in the insulin receptor gene, although currently available data are consistent with estimates that about 1% of patients with T2DM may have such mutations in their receptor gene.^{180,181} In several instances the same mutation has been identified in two apparently unrelated patients. However, most of the published mutations have only been identified in single kindreds. The mutations have been separated into five classes based on the mechanisms that impair insulin receptor function (Fig. 21-26). This approach is a modification of the scheme proposed by Brown and Goldstein for the LDL receptor.²⁸⁶

Class 1: Impaired Receptor Biosynthesis

Several types of premature chain termination mutations have been identified in the insulin receptor gene (Fig. 21-27): nonsense

Class of Mutation	Synthesis	Transport to Plasma Membrane	Insulin Binding	Trans-membrane Signalling	Endocytosis, Recycling, Degradation
①	→ x				
②		→ x			
③			→ x		
④				→ x	
⑤					→ x

FIGURE 21-26. Classification of mutations in the insulin receptor gene. This drawing illustrates the major steps in the life of an insulin receptor. First, the gene is transcribed, and the RNA is spliced. The mature mRNA is transported from the nucleus to the cytosol where it is translated by ribosomes on the rough endoplasmic reticulum. The receptor is transported through the endoplasmic reticulum and Golgi complex, the organelles that cause it to undergo multiple posttranslational modifications. Eventually the mature receptor is inserted in the plasma membrane. Insulin binds to the receptor on the cell surface. As a result, the receptor undergoes autophosphorylation and becomes activated as a tyrosine kinase. The interaction of insulin with its receptor initiates the various responses of the target cell to insulin. In addition, insulin binding triggers receptor endocytosis. The acid pH in the endosome dissociates insulin from its receptor. Subsequent to receptor internalization, the receptor is either transported to lysosomes for degradation or recycled back to the plasma membrane for reutilization. The five major classes of genetic defects in receptor function are summarized in the table at the bottom of the figure. This classification scheme is based on the classification for genetic defects in the function of the low-density lipoprotein receptor originally proposed by Brown and Goldstein.²⁸⁶ (Reproduced with permission from Taylor.¹⁸¹)

mutations,^{274,276,277} mutations at intron-exon junctions that impair splicing of mRNA,²⁸⁷ and deletion mutations that shift the reading frame.^{281,288} Premature chain termination mutations interfere with receptor biosynthesis, and lead to the synthesis of truncated receptor fragments. In addition, most premature chain termination mutations exert a *cis*-acting effect to decrease the level of mRNA transcribed from the mutant allele.^{274,277} In some patients, mutant alleles have been demonstrated to decrease the level of insulin receptor mRNA, but the mutations map outside the protein coding regions, most likely in regions of the gene that regulate its level of expression.^{277,289} At least one patient with leprechaunism has been reported who was homozygous for a total deletion of both insulin receptor genes,²⁷⁵ and several patients were homozygous for other null alleles.²⁹⁰⁻²⁹³

Class 2: Impaired Transport of Receptors to the Cell Surface

The insulin receptor precursor undergoes multiple posttranslational processing steps within the endoplasmic reticulum and

Golgi complex. Some mutations impair transport through the endoplasmic reticulum and Golgi to the plasma membrane, thereby reducing the number of receptors on the cell surface.^{93,180,181,281,283,294-297} Because these mutations prevent the receptor from folding into its normal conformation, some class 2 mutations also impair receptor function, e.g., decreasing the affinity of insulin binding²⁹⁶ or inhibiting activation of the receptor tyrosine kinase.²⁹⁴ Most of the published mutations in this class are located in the N-terminal half of the α subunit. However, at least one mutation that inhibited posttranslational processing of the proreceptor and transport of the receptor to the plasma membrane was located in the intracellular domain and inhibited receptor tyrosine kinase activity.²⁹⁸

Class 3: Decreased Affinity of Insulin Binding

Some mutations decrease the affinity with which the receptor binds insulin.^{180,181} This is predicted to cause a rightward shift in the dose-response curve for insulin action, i.e., to decrease the sensitivity with which the target cell responds to insulin. A mutation substituting serine for arginine (R735S) was the first mutation reported to decrease the affinity of insulin binding.^{282,299} Arg735 is the last amino acid in the Arg-Lys-Arg-Arg motif at the proteolytic cleavage site between the α and β subunits. In addition to decreasing the affinity of insulin binding, the R735S mutation inhibits cleavage of the precursor into two subunits.

Two mutations in the N-terminal half of the α subunit have also been reported to decrease the affinity of insulin binding, consistent with the hypothesis that the insulin binds to this region of the receptor.^{93,180,181} The N15K mutation causes a fivefold reduction of affinity, and the S323L mutation essentially abolishes insulin binding.^{284,300,301}

Class 4: Impaired Tyrosine Kinase Activity

Many mutations have been identified in the tyrosine kinase domain that inhibit receptor tyrosine kinase activity. The G1008V mutation was among the first mutations to be identified in this domain.³⁰² Valine is substituted for Gly1008, the third glycine in the highly conserved Gly-X-Gly-X-X-Gly motif in the ATP binding site. Because ATP is the phosphate donor for the tyrosine kinase reaction, it is not surprising that a mutation in the ATP binding site inactivates the tyrosine kinase. Unlike most mutations in the extracellular domain of the insulin receptor, mutations in the tyrosine kinase domain cause insulin resistance in a dominant fashion.^{93,180,181}

Class 5: Accelerated Receptor Degradation

Insulin binding triggers endocytosis of the insulin-receptor complex.³⁰³ Internalized receptors are located in endosomes with the insulin-binding site oriented on the inside of the vesicle.³⁰⁴ Endosomal proton pumps acidify the interior of the endosome (pH 5.5), and the acidic pH promotes dissociation of insulin from the receptor.³⁰⁵ Subsequent to internalization, there are at least two pathways available to the receptor: recycling back to the plasma membrane for reutilization and degradation within the lysosome. Some mutations (i.e., K460E and N462S) impair the ability of acidic pH to dissociate insulin from the receptor.^{276,305,306} Both mutations are associated with an impaired recycling pathway and preferential targeting of mutant receptors toward lysosomal degradation, thereby accelerating receptor degradation and decreasing the number of receptors on the cell surface.^{276,305,307} Receptor mis-sense mutations from classes 2-5 are shown in Fig. 21-28.

FIGURE 21-27. Mutations that impair receptor biosynthesis (class I). In this drawing of the receptor, the structural landmarks are indicated on the left side of the figure. Examples of class I mutations are indicated on the right side of the figure. These include nonsense mutations, as well as frameshifts and splicing mutations. (In the right half of the drawing, the tetrapeptide connecting the two subunits has not been removed in order to illustrate the sequence of the uncleaved proreceptor.) (Modified from and based on Taylor SI, Arioglu E: *Syndromes associated with insulin resistance and acanthosis nigricans*. *J Basic Clin Physiol Pharmacol* 1998;9:419. Used with permission.)

Correlation of Molecular Defects with Clinical Syndromes

At least three different theories have been considered to explain the fact that mutations in the insulin receptor gene cause several distinct clinical syndromes.¹⁷⁹⁻¹⁸¹

Severity of Insulin Resistance

According to this hypothesis, the severity of insulin resistance determines the clinical manifestations. Patients with leprechaunism have mutations in both alleles of the insulin receptor gene,^{180,181} and exhibit the most extreme degree of insulin resistance. In contrast, heterozygosity for a single mutant allele causes the less severe syndrome of type A insulin resistance. Furthermore, even among patients with type A insulin resistance, the patients with two mutant alleles have a more severe form of the syndrome, characterized by fasting hyperglycemia.

Existence of Branched Pathways

Insulin is a hormone that has multiple biologic actions. The pathways for insulin action diverge in the biochemical steps distal to the receptor. According to this hypothesis, the effect of a mutation would depend on which biologic actions are impaired and which are preserved.³⁰⁸ For example, a mutation that impairs both the metabolic actions and the growth-promoting effects of insulin might cause leprechaunism (a syndrome with growth retardation as well as abnormal glucose tolerance). If a mutation selectively impairs only the ability of the receptor to mediate the metabolic actions of

insulin, this might cause type A insulin resistance (a syndrome with abnormal glucose tolerance but normal growth).

Genetic Variation at Different Loci

According to this theory, the insulin receptor locus is the major disease gene responsible for the insulin resistance, but other genetic loci modulate the clinical syndrome. For example, defects in various growth factor receptors have been reported in patients with leprechaunism, and these defects may contribute to the growth retardation associated with the syndrome.³⁰⁹ However, if the difference between type A insulin resistance and leprechaunism were due to mutations at another genetic locus, then one would predict that mutations at the two genetic loci would segregate independently. If a child inherited the insulin receptor mutations in the absence of the mutations at the other locus, the patient would manifest type A insulin resistance. If another child in the same pedigree inherited mutations in both the insulin receptor and the other locus, then that child would develop leprechaunism. This pattern of inheritance has not been reported, although many kindreds have been reported with two or more siblings having the same clinical syndrome (i.e., either leprechaunism or type A insulin resistance).

Nevertheless, it is likely that polygenic influences may explain some clinical variation between individuals with the same genotype at the insulin receptor locus. Two sisters with type A insulin resistance (both homozygous for the F382V mutation) illustrate this clinical variability in the syndrome.^{283,310,311} Although the

FIGURE 21-28. Missense mutations in the insulin receptor gene. Examples of missense mutations in the insulin receptor gene are indicated in the figure. These mutations either impair the transport of receptors to the plasma membrane (class 2), decrease the affinity of insulin binding (class 3), impair tyrosine kinase activity (class 4), or accelerate the rate at which receptors are degraded (class 5). (Modified from and based on Taylor SI, Arioglu E: *Syndromes associated with insulin resistance and acanthosis nigricans*. *J Basic Clin Physiol Pharmacol* 1998;9:419. Used with permission.)

younger sister required treatment with several thousand units of insulin per day, the older sister responded to dietary management. The younger sister had such severe hyperandrogenism that she had never menstruated spontaneously and did not experience withdrawal bleeding when treated with estrogen-progestin, while the older sister twice became pregnant.

Insulin Resistance

Jerrold M. Olefsky

Yolanta T. Kruszynska

In 1889 Mering and Minkowski¹ demonstrated that total pancreatectomy in dogs was followed by hyperglycemia, glycosuria, ketosis, and death. The similarity between this syndrome and diabetes mellitus was noted, and this suggested that diabetes mellitus was due to pancreatic deficiency. Following this, Banting and Best^{2,3} published their classic studies in which they showed that the sequelae of total pancreatectomy could be controlled if dogs were treated with parenteral injections of a pancreatic extract obtained following ligation of the pancreatic ducts. Because of the enormous importance of these studies, most scientists in the field came to the conclusion that all human diabetes was entirely due to insulin deficiency. Despite this apparent consensus, it is important to realize that 27 years after the discovery of insulin, Himsworth⁴ pointed out "that in the diabetic patient insulin appears to vary in efficiency at different times." He suggested that diabetes could be differentiated into "insulin sensitive" and "insulin insensitive" types on the basis of the blood glucose response to insulin administered immediately following an oral glucose load.

Continuing this line of investigation, Himsworth published the accumulated evidence in support of his notion that insulin insensitivity, and not insulin deficiency, was present in many patients with diabetes. He further suggested that the classification of patients with diabetes into two groups corresponded to the clinical forms of diabetes: patients who are insulin-sensitive tended to be ketosis-prone, while the middle-aged, nonketotic diabetic tended to be insulin-insensitive. In 1960 Yalow and Berson published their study of the immunoassay of endogenous plasma insulin in humans.⁵ These results demonstrated that plasma insulin was indeed measurable in diabetic patients, and that on average, higher levels existed in the subjects with the adult-onset form of the disease. This term generally corresponds to the new classification of non-insulin-dependent (NIDDM) or type 2 diabetes mellitus (T2DM). On the basis of these results, they concluded "that the tissues of the maturity onset diabetic do not respond to insulin as well as the tissues of the non-diabetic subjects respond to insulin."

Since that time, plasma insulin levels have been measured many times under a variety of circumstances in diabetic patients. Rabinowitz and Zierler⁶ provided the first direct evidence of insulin resistance in man when they demonstrated that intra-arterial administration of insulin produced significantly less glucose uptake by forearm muscle in obese subjects than in normal individuals. In addition, newer techniques have been devised to directly estimate *in vivo* insulin action in a number of clinical and patho-

physiologic states. From these studies it is now clear that resistance to the action of insulin is a characteristic feature of human obesity and non-insulin-dependent, or type 2, diabetes mellitus. In addition to these common clinical conditions, insulin resistance is also present in several unusual but well-defined syndromes such as acromegaly and lipodystrophy. In this chapter, the general problem of insulin resistance and its mechanisms will be discussed, and then we will turn to specific issues related to obesity and diabetes mellitus. Relatively less attention will be paid to the unusual syndromes of insulin resistance.

GENERAL CONSIDERATIONS

Insulin is produced in the pancreatic β cell as the primary biosynthetic product preproinsulin. Preproinsulin is rapidly converted to proinsulin (MW $\sim$ 9000), most of which is cleaved into insulin (MW $\sim$ 6000) and C peptide with only about 5% remaining as proinsulin. Insulin is secreted in response to a number of stimuli with glucose being the most important. After a brief circulating time ($t_{1/2}$, 5–10 minutes), the hormone interacts with a specific receptor on target tissues to exert its biologic effects.

Insulin resistance is a state in which a given concentration of insulin produces a less than normal biologic response. Because one of insulin's major effects is to promote overall glucose metabolism, abnormalities of this action of insulin can lead to a number of important clinical and pathophysiologic states. Because insulin travels from the β cell through the circulation to the target tissue, events at any one of these loci can influence the ultimate action of the hormone. Therefore, it is useful to categorize insulin resistance according to known etiologic mechanisms (Table 22-1). In general, insulin resistance can be due to (1) an abnormal β -cell secretory product, (2) circulating insulin antagonists, or (3) a target tissue defect in insulin action. Subclassifications exist within each of these categories.

CAUSES OF INSULIN RESISTANCE

Abnormal β -Cell Secretory Product

Several patients have been described who secrete a structurally abnormal, biologically defective insulin molecule as a result of a mutation in the structural gene for insulin.^{7–9} Others have been

TABLE 22-1. Causes of Insulin Resistance

Abnormal β -cell secretory product
Abnormal insulin molecule
Incomplete conversion of proinsulin to insulin
Circulating insulin antagonists
Elevated levels of counterregulatory hormones, (e.g., growth hormone, cortisol, glucagon, or catecholamines)
Elevated free fatty acid levels
Anti-insulin antibodies
Anti-insulin receptor antibodies
Resistin
Cytokines (TNF- α , interleukin 6)
Target tissue defects
Insulin receptor defects
Postreceptor defects

described with familial hyperproinsulinemia, caused by incomplete conversion of proinsulin to insulin within the β -cell secretory granule as a result of structural abnormalities at the proteolytic cleavage sites of the proinsulin molecule.^{10,11} These syndromes are dealt with in more detail in Chaps. 3 and 21 and will not be discussed further here, except to note that they do not represent insulin-resistant states in the most common usage of the term. Thus in these syndromes it is the hormone that is abnormal and the patients are only resistant to their endogenous insulin and not to exogenous insulin.

Circulating Insulin Antagonists

Circulating antagonists may be hormonal or nonhormonal.

Hormonal Antagonists

Hormonal antagonists include all of the known counterregulatory hormones such as cortisol, growth hormone, glucagon, and catecholamines. Well-known clinical syndromes exist (Cushing's disease, pheochromocytoma, glucagonoma, acromegaly) in which elevated levels of these hormones can induce an insulin-resistant diabetic state (see Chap. 25). However, in the usual case of obesity or T2DM, excessive levels of counterregulatory hormones are not an important contributory factor to insulin resistance.

Glucocorticoids

It is well known that excess endogenous or exogenous glucocorticoids impair carbohydrate metabolism, and this is often referred to as *steroid diabetes*. This effect is perhaps best exemplified in patients with Cushing's syndrome. In these patients, carbohydrate tolerance is often impaired. However, fasting hyperglycemia and overt symptomatic diabetes occur in less than 20% of patients, and the abnormalities of carbohydrate tolerance are generally limited to those that can be elicited only through the stress of a glucose challenge. Analogous results are seen in patients who receive exogenous glucocorticoids. In a patient with normal baseline carbohydrate tolerance, the usual effect of glucocorticoid administration will be some degree of deterioration of the ability to respond to a glucose load. Analysis of glucose tolerance tests after treatment with glucocorticoids reveals increased plasma insulin values accompanied by only mild to moderate increases in glucose concentration.¹² This pattern of glucose intolerance—increased glucose concentrations in the face of increased insulin concentrations—is characteristic of an insulin-resistant state.

A number of mechanisms cause this decrease in insulin action, since glucocorticoids counteract the effects of insulin at several steps in glucose homeostasis. Hepatic glucose output increases in some patients with Cushing's syndrome,¹³ as well as after infusion of cortisol,¹⁴ and the liver becomes resistant to the normal suppressive effect of insulin on hepatic glucose output.¹⁴ Glucocorticoids increase the activity of key hepatic gluconeogenic enzymes¹⁵ and the release of gluconeogenic substrates (amino acids, lactate, and glycerol) from peripheral tissues.^{16–18} Both increased substrate availability and increased hepatic ability to produce glucose from substrates are involved in the glucocorticoid-induced increase in hepatic glucose production. Furthermore, glucocorticoid treatment raises plasma glucagon levels,^{16,19} which also augments hepatic glucose production. Glucocorticoids can also decrease peripheral glucose utilization.¹⁴ Again, this effect is mediated through several mechanisms. Corticosteroids decrease the activity of the plasma membrane glucose transport system by decreasing the transport $V_{\max}$.²⁰ They appear to do this by inhibiting the ability of insulin to mediate the recruitment, or translocation, of glucose transport proteins from the cell interior to the cell surface.²¹ Additionally, some glucocorticoids can cause a decrease in insulin binding to receptors, both *in vivo* and *in vitro*; this is mediated through a decrease in both receptor affinity^{22,23} and number.²² *In vivo*, the effects of glucocorticoids that cause insulin resistance have been well documented using the glucose clamp technique; they reduce the effect of insulin at all insulin concentrations¹⁴ and also markedly slow the rate of activation of insulin's *in vivo* biologic effects.²⁴ Insulin secretory abnormalities have also been reported after steroid treatment (see Chaps. 21 and 25).

Growth Hormone

Growth hormone is a well-recognized circulating insulin antagonist. In chronic excess it can lead to carbohydrate intolerance.²⁵ Acromegaly can be associated with hyperinsulinemia, glucose intolerance, and decreased effectiveness of exogenous insulin. In most cases of acromegaly, compensatory hyperinsulinemia is sufficient to prevent gross deterioration of glucose homeostasis. Thus mild abnormalities of glucose tolerance are the rule, and less than 20% of patients develop fasting hyperglycemia.²⁵ The mechanism underlying the anti-insulin effects of growth hormone has not been clearly elucidated, in part due to the multiplicity of cellular effects of growth hormone and the heterogeneity of circulating forms of the hormone. Although excess growth hormone clearly leads to an insulin-resistant state in the chronic situation, the acute effects of growth hormone on insulin action are less clear. For example, *in vitro* the acute effects of growth hormone can be anabolic and insulin-like. Early *in vivo* studies showed that infusion of growth hormone leads to hyperinsulinemia and higher plasma glucose levels after an oral glucose load, suggesting insulin resistance;²⁶ fasting plasma free fatty acid and ketone body levels are also increased despite the hyperinsulinemia.²⁶ Most studies have shown that growth hormone leads to an impairment of insulin-stimulated glucose uptake and may also impair insulin's ability to suppress hepatic glucose output.^{25,27,28} These effects develop 2–12 hours after exposure to high growth hormone levels and are most marked at submaximally stimulating insulin concentrations.²⁷ An additional major effect of this hormone is to induce the production of insulin-like growth factor 1 (IGF-1), and IGF-1 has its own cellular effects. Finally, insulin secretory abnormalities have also been reported. For a more detailed discussion of this subject the reader is referred to Chaps. 21 and 25.

Catecholamines

Excessive levels of circulating catecholamines can also antagonize the effects of insulin, and several mechanisms are involved. Catecholamines can stimulate glucagon secretion (β -effect) and increase hepatic glucose production by direct stimulation of glycogenolysis and gluconeogenesis (α - and β_2 -effect). In combination, these effects tend to cause hyperglycemia and are opposite to the actions of insulin. Additionally, catecholamines directly inhibit peripheral glucose uptake (β -effect), and this has been demonstrated both *in vitro* in isolated adipocytes²⁹ and *in vivo* using the glucose clamp technique.^{30,31} It is also possible that in addition to direct insulin antagonistic effects, the β -adrenergic-induced augmentation of lipolysis³¹ leads to a secondary fatty acid-induced decrease in glucose uptake, at least *in vivo*. Catecholamines also impair β -cell insulin secretion by an α -adrenergic effect (see Chaps. 9, 21, and 25).

Placental Lactogen

Lactogen is a placental-derived hormone that may be causally involved in the insulin resistance that develops during the late second and third trimesters of normal pregnancy. Other than its potential role in the development of gestational diabetes, this hormone has little relevance to obesity or T2DM. Its mechanisms of action are not understood.

Glucagon

Glucagon influences glucose metabolism by augmenting hepatic glycogenolysis and gluconeogenesis, and in this sense, glucagon can counteract some of insulin's effects. However, glucagon has no influence on insulin's ability to promote peripheral glucose metabolism and does not lead to a true state of insulin resistance. For a detailed discussion of glucagon action, the reader is referred to Chap. 7.

Nonhormonal Antagonists

Free Fatty Acids

Fasting plasma free fatty acid (FFA) levels tend to be higher in type 2 diabetic patients than in lean normal subjects, and suppression of FFA levels after meals is impaired. These abnormalities are more marked in type 2 diabetic patients with significantly impaired insulin secretion and in obese patients. Elevated FFA levels are also found in other insulin-resistant states such as cirrhosis, uremia, and sepsis. A number of years ago Randle and coworkers³² showed that FFAs could compete with glucose for oxidative metabolism in skeletal muscle and heart muscle. They hypothesized that elevated circulating levels of FFAs could impair peripheral glucose use. Studies using the glucose clamp technique have confirmed that elevated FFAs can induce mild insulin resistance.^{33–36} However, the intracellular mechanism may differ from that originally proposed.³² Thus, according to Randle's hypothesis, the inhibition of glucose oxidation and glycolysis as a result of enhanced cellular FFA uptake would lead to increased intracellular glucose-6-phosphate levels, which in turn would inhibit the phosphorylation of incoming glucose and hence glucose uptake. It now appears that the decreased glucose uptake that develops after several hours of raised plasma FFA levels must involve additional direct effects of FFAs on insulin-stimulated glucose transport. Evidence for this comes from the finding that when plasma FFA levels were elevated during a hyperinsulinemic glucose clamp in normal subjects, gastrocnemius muscle glucose-6-phosphate levels progressively decreased instead of

increasing,³⁵ as did intracellular free glucose levels.³⁶ These findings strongly suggest that prolonged elevation of FFA levels impairs insulin-stimulated muscle glucose transport. Recent data indicate that the mechanism may involve FFA-induced defects at several early steps in the insulin signaling pathway, including decreased activation of phosphatidylinositol-3-kinase (PI-3-kinase), which is thought to be important for insulin's enhancement of glucose transport.^{36,37} These effects of FFAs may be mediated by accumulation of long-chain fatty acyl coenzyme A.

Skeletal muscle also uses FFAs from intramuscular triglyceride depots. Increased circulating FFA levels might be expected to promote the accumulation of triglycerides within the muscle if their supply exceeds immediate energy needs. Skeletal muscle triglyceride levels in nondiabetic subjects correlate inversely with whole-body insulin sensitivity and are a better predictor of insulin sensitivity than either body mass index or percentage of body fat.^{38,39} Muscle triglyceride levels are increased in type 2 diabetic patients.⁴⁰ Moreover, insulin-resistant offspring of type 2 diabetic patients have a much higher intramyocyte lipid content than do insulin-sensitive offspring matched for age, body mass index, physical activity, and percentage of body fat.^{39,41}

Support for the hypothesis that increased availability of FFAs may contribute to insulin resistance and glucose intolerance also comes from studies using acipimox, a long-acting nicotinic acid analogue that potently inhibits lipolysis. When obese type 2 diabetic and nondiabetic subjects were treated with this drug, FFA levels were reduced well into the normal range, and this was associated with an improvement in oxidative and nonoxidative glucose metabolism. However, these were not normalized and the improvement in oral glucose tolerance was rather modest. Whether further improvements in glucose metabolism might be seen with prolonged treatment that normalizes hepatic and muscle fat levels as well as circulating FFA levels remains to be seen. FFAs also play an important role in the regulation of hepatic glucose output and may contribute to hepatic insulin insensitivity in obesity and T2DM. This is discussed later in this chapter. Available evidence indicates that increased FFAs may contribute to both hepatic and peripheral tissue insulin insensitivity, but that FFAs probably explain only a portion of the defect in carbohydrate metabolism that exists in T2DM.

Anti-Insulin Antibodies

Essentially all patients who receive animal-derived insulin for a long enough period of time eventually develop anti-insulin antibodies. In past years, insulin preparations were commonly a mixture of beef and pork insulins, and the antigenicity of these preparations has been related to the insulin as well as the impurities within the mixture. In more recent years, highly purified insulins have been available and these have proven to be much less antigenic. With the use of these newer preparations, the development of anti-insulin antibodies is much less of a problem than in the past. However, even with completely pure beef or pork insulin, some antigenicity would still exist, since there are structural differences between human and pork or beef insulin. Pork insulin differs from human insulin only at a single residue: B 30 is threonine in human and alanine in pork insulin. Beef insulin differs from human insulin at three amino acid residues, including the region of the intra-A-chain disulfide bridge, and this has a significant effect on the tertiary structure of beef insulin. This explains the reduced antigenicity of pork insulin versus beef, and most anti-insulin sera have a lower affinity for pork insulin compared with beef. With the more recent

use of highly purified human insulin made by either recombinant or chemical methods, the problem of insulin antibodies has become even less of an issue, although low titers of insulin antibodies have been noted even in patients treated only with pure human insulin. The immunogenicity of an insulin preparation may be influenced by the route of insulin delivery. Thus insulin infused intraperitoneally appears to be more immunogenic than subcutaneously infused insulin.⁴²

Although anti-insulin antibodies do not usually lead to a clinically significant insulin-resistant state, the presence of these antibodies alters the pharmacokinetics of insulin.^{43,44} High titers of high-affinity antibodies can act as a reservoir for insulin by binding the hormone when it initially enters the circulation and later releasing it. This increases the half-life of circulating insulin^{43,44} and prolongs the time course of insulin action.⁴⁵

Anti-Insulin Receptor Antibodies

In a few well-documented cases, circulating endogenous immunoglobulins directed against the insulin receptor have been described in insulin-resistant diabetic patients.^{46,47} This syndrome is extremely rare and is discussed in more detail later in this chapter. Possibly, patients will be discovered with antibodies against other critical proteins in the insulin action scheme, such as the glucose transporter.

Resistin

Resistin is a novel protein secreted by adipocytes that circulates in plasma and has been shown to antagonize some of the metabolic actions of insulin.⁴⁸ Levels decrease with prolonged fasting and increase with refeeding. Acute administration of resistin to normal mice resulted in higher blood glucose and insulin responses to an oral glucose load and a blunted hypoglycemic response to exogenous insulin. Conversely, administration of antiresistin antibody to mice that became insulin resistant and glucose intolerant on a high-fat diet resulted in improved insulin sensitivity and glucose tolerance. These findings, and the observation that plasma resistin levels were increased in the genetically obese *db/db* and *ob/ob* mice, and in mice that developed obesity and insulin resistance after 8 weeks on a high-fat diet,⁴⁸ suggest that resistin could provide a link between obesity, insulin resistance, and T2DM.

Other Insulin Antagonists

Over the years a variety of antagonist activities have been reported in plasma of type 2 diabetic subjects. However, none of these earlier "insulin resistance factors" have been isolated and chemically identified, and thus cannot be substantiated, although reports continue to appear.⁴⁹ One such factor is islet amyloid polypeptide (IAPP). IAPP has a high degree of homology to calcitonin gene-related peptide (CGRP), and is cosecreted with insulin from the islet β cell (see Chaps. 17 and 21). It can inhibit insulin-stimulated glucose uptake when pharmacologic doses are infused.^{50,51} However, subsequent studies have shown no anti-insulin actions of IAPP at high physiologic doses.⁵² Furthermore, transgenic mice have been produced that overexpress the human IAPP gene, leading to markedly elevated circulating concentrations of IAPP. These animals were not hyperglycemic, nor were they hyperinsulinemic or insulin resistant.⁵³ Based on these studies, it seems unlikely that circulating IAPP plays a significant role in causing insulin resistance in human disease. In fact, IAPP may have a beneficial role in glucose homeostasis because it inhibits postprandial glucagon secretion and gastric emptying.^{51,54}

Cytokines

Cytokines such as tumor necrosis factor- α (TNF- α) and interleukin-6 (IL-6) may contribute to the insulin resistance associated with sepsis, cirrhosis, or other severe illness. Recent studies have raised the provocative idea that they may also play a role in the insulin resistance of obesity and T2DM.⁵⁵⁻⁵⁷ TNF- α is produced in adipose tissue, and elevated amounts of TNF- α are produced in a variety of genetic forms of obesity in animal models.^{55,57} *In vitro* studies have shown that TNF- α can impair insulin receptor signaling.⁵⁸ Furthermore, neutralization of TNF- α by *in vivo* administration of soluble TNF- α receptors or TNF- α antibodies greatly ameliorated the insulin resistance in obese animals.⁵⁵⁻⁵⁷ However, in obese type 2 diabetic patients, intravenous infusion of an antibody that neutralizes TNF- α had no effect on insulin resistance.^{56,59} Thus if excess adipocyte production of TNF- α in obesity contributes to insulin resistance, it probably does so not in an endocrine fashion, but in a local autocrine or paracrine fashion. This is an interesting hypothesis, but one which will require considerable future experimentation before the role of TNF- α in human pathophysiologic states characterized by insulin resistance will be fully understood.

IL-6 is another cytokine that has recently been suggested to play a role in the insulin resistance of obesity and type 2 diabetes.^{60,61} IL-6 is produced by adipocytes as well as immune cells and circulating levels are increased in obesity and T2DM. As well as stimulating the hypothalamic-pituitary-adrenal axis, it also has direct effects on adipocyte metabolism. A C $\rightarrow$ G polymorphism at -174 in the IL-6 gene was found to be associated with higher IL-6 gene transcription and IL-6 secretion rates from adipocytes, and healthy carriers of this polymorphism had a twofold increase in fasting triglyceride and FFA levels. Postprandial FFA levels were also elevated.⁶² Thus IL-6 could contribute to insulin resistance through its effects on adrenal steroid production or as discussed above through a chronic elevation of plasma FFA levels.

GENERAL CONSIDERATIONS OF INSULIN ACTION

Before considering cellular causes of insulin resistance, it is useful to review some of the general concepts concerning normal and abnormal insulin action. Figure 22-1 presents a schematic diagram of cellular insulin action. The first step involves binding of insulin to specific cell surface receptors. The amino acid sequence of the receptor has been deduced from the cloned insulin receptor cDNA and consists of two identical α subunits and two β subunits, all linked together by disulfide bonds to form the full heterotetrameric structure.⁶³⁻⁶⁶ The α subunits are entirely extracellular, whereas the β subunits have an extracellular, transmembrane, and cytoplasmic domain. The α subunit contains the insulin binding site, and after the hormone binds, a transmembrane signal is generated which initiates the insulin action program. The first known event following binding of insulin to its receptor is stimulation of a tyrosine kinase enzymatic activity intrinsic to the β subunit. Once activated, the β subunit undergoes an autocatalytic reaction (autophosphorylation) in which specific tyrosine residues within the subunit are phosphorylated.⁶⁴⁻⁶⁷ As a result of autophosphorylation the tyrosine kinase activity of the receptor β subunit is enhanced⁶⁴⁻⁶⁷ such that it can now phosphorylate tyrosine residues on endogenous phosphoprotein substrates, such as insulin receptor substrate-1 (IRS-1) (see below). A substantial body of evidence has accumulated indicating

FIGURE 22-1. Model of insulin action. Abnormalities can occur at the pre-receptor phase, involving biosynthesis and secretion of abnormal β -cell products; at the receptor binding phase, involving decreased insulin binding to receptors due to decreased receptor number or affinity; or at the postreceptor binding phase, involving any defect in the insulin action cascade distal to the initial binding event.

that the receptor kinase is a critical initial step in a variety of insulin's biologic effects. For example, it has been shown by site-directed mutagenesis of the insulin receptor cDNA that a kinase-defective mutant insulin receptor can be made which, after transfection into host cells, is incapable of mediating insulin's bioeffects.^{66,68,69} Additionally, intracellular injection of antiphosphotyrosine antibodies effectively blocks insulin action.⁷⁰

Activation of the receptor initiates a signaling cascade which culminates in the metabolic and growth effects of insulin. Considerable progress has been made in elucidating the mechanisms by which the insulin signal is transmitted downstream from the activated insulin receptor to the various insulin-regulated enzymes, transporters, and insulin-responsive genes (Fig. 22-1). This complex and rapidly evolving field is discussed only briefly as it is covered in detail in Chap. 5. A number of cytosolic protein substrates of the insulin receptor kinase have been reported. The first of these to be identified as a key player in the insulin signaling pathway was insulin receptor substrate-1 (IRS-1).^{66,67} It belongs to a growing family of proteins that also includes IRS-2, IRS-3, IRS-4, and a protein called shc. All of these are immediate substrates of the insulin receptor kinase and are involved in insulin signaling in different cells. A shared characteristic of these proteins is that they have no enzymatic activity, but instead act as docking proteins. Thus when tyrosine phosphorylates, they can associate with other proteins that contain src homology-2 (SH2) domains.^{66,67} The latter are sequences of approximately 100 amino acids that can bind to specific short sequences that encompass a phosphotyrosine moiety. When specific SH2 domain-containing downstream signaling proteins bind to tyrosine phosphorylated IRS proteins or shc, a large multicomponent signaling complex is formed, leading ultimately to the modulation of the activities of lipid kinases, serine and threonine kinases, and phosphatases that act on insulin-regulated enzymes and transcription factors. Recent evidence indicates that insulin receptors can phosphorylate G α q/11, which would provide a mechanism for modulation of G protein signaling to glucose transport.⁷¹ It is now clear that a number of signaling pathways diverge at different points in the insulin action cascade. For example, the

mitogenic and metabolic actions of insulin are mediated by distal pathways downstream of the insulin receptor kinase, and even a single action of insulin, such as activation of glucose transport, may involve more than one signaling pathway.⁷² Although tyrosine phosphorylation is a critical early step in insulin action, other signaling processes may either modulate the phosphorylation mechanism or separately mediate specific insulin effects. These may include the generation of various second messengers such as diacylglycerol, phosphoinositide-glycans, or changes in ion flux proteins, and the like.⁷³

Regardless of the precise nature of the signaling mechanism, it eventually interacts with a variety of effector units, which mediate the entire host of biological actions attributable to insulin. In many instances the effector unit consists of a series of steps such as a sequentially linked enzyme system (the glycogen synthase phosphorylase system) or a series of enzymes involved in the degradation of a particular substrate (glucose). Clearly, insulin action involves a cascade of events, and abnormalities anywhere along this sequence can lead to insulin resistance. For convenience, cellular abnormalities in insulin action can be categorized under the headings of binding and postbinding defects.

Decreased cellular insulin receptors have been described in a variety of pathophysiologic situations. The most common of these are obesity⁷⁴⁻⁷⁶ and T2DM.⁷⁵⁻⁷⁹ Decreased insulin receptors have also been described in acromegaly,⁸⁰ following glucocorticoid⁸¹ or oral contraceptive therapy,⁸² and in several other less common conditions.^{83,84} Since the first step in insulin action involves binding to the receptor, it is apparent that a decrease in cellular insulin receptors could lead to insulin resistance. However, this potential relationship is not as clear as it would seem because insulin target tissues possess "spare" receptors.^{85,86}

The spare receptor concept is based on the observation that maximal insulin effect is achieved at a concentration of insulin at which less than the total number of cellular receptors are occupied. For example, for glucose transport in adipocytes and muscle, maximal response is achieved with only 10–20% of the receptors occupied. Thus 80–90% of the normal complement of receptors are "spare." All of these spare receptors are potentially fully functional, but which receptors are occupied at any given time is purely a random event; any group of occupied receptors amounting to 10–20% of the total would lead to the same metabolic response. Therefore, the cellular response to increasing insulin concentration is a continuous increase in receptor occupancy and biologic action until the critical number of occupied receptors needed to generate a maximal response is reached. Further increases in the prevailing insulin concentration beyond this point lead to a continued increase in receptor occupancy with no further increase in biological response, since a step distal to the receptor is now rate-limiting. The predicted functional consequence of a decrease in the number of receptors is a rightward shift in the dose-response curve for insulin action (i.e., a decreased response at lower insulin concentrations, but a normal response at maximally effective hormone concentrations).^{76,85,87} This is illustrated in Fig. 22-2. The degree of rightward shift of the insulin dose-response curve is proportional to the decrease in the number of receptors. The only time a decrease in the number of insulin receptors can lead to a decrease in maximal insulin action is when less than 10–20% of the original receptor complement is present (Fig. 22-2). The proportion of spare receptors varies according to cell type and is also dependent upon which action of insulin is measured.

FIGURE 22-2. Predicted functional consequence of a progressive loss of insulin receptors on the insulin biologic function dose-response curve. Results represent theoretical dose-response curves in which the percentage of the maximal insulin effect (**left axis**) and the percentage of the normal maximal amount bound (**right axis**) are plotted as a function of insulin concentration. With progressive receptor loss, the dose-response curves are increasingly shifted to the right with no change in maximal insulin action, although more insulin is necessary to elicit a maximal insulin response. If enough receptors are lost (95%) so that 5% of the original receptor complement is present, both a rightward shift in the dose-response curve and a decrease in maximal insulin response occur.

It is apparent that the overall scheme of insulin action represents a multistep sequence in which the binding of insulin to receptors is only the initial event. A defect in any of the effector systems distal to receptor binding can also lead to impaired insulin action and insulin resistance. These defects can involve abnormal coupling between insulin-receptor complexes and the effector system (e.g., glucose transport), decreased activity of the effector system *per se*, or a variety of intracellular enzymatic defects. In this context the term *postbinding defect* refers to any abnormality in the insulin action sequence following the initial insulin-receptor binding event. This defect could include an abnormality of the insulin receptor that does not affect insulin binding but does affect the transmembrane signaling function of the receptor (e.g., β -subunit kinase activity), or any defect in the insulin action sequence distal to the receptor. The latter can be termed a *postreceptor defect* and generally refers to abnormalities in effector proteins such as the glucose transporter or target enzymes. The most common type of postreceptor defect leads to a proportionate decrease in insulin action at all insulin concentrations, including maximally effective hormone levels.^{76,87} Thus a decrease in the capacity of a rate-limiting step in the insulin action-glucose metabolism scheme leads to a reduction in the maximal insulin effect, and this defect cannot be overcome by the addition of more insulin.

On the basis of our understanding of normal insulin action, the effects of binding versus postbinding defects on the *in vivo* insulin biologic function dose-response curve can be predicted, and by studying the insulin dose-response curve in insulin-resistant states the following distinctions, which are summarized in Fig. 22-3, can be made.

1. An isolated decrease in the number of insulin receptors leads to a rightward shift in the insulin dose-response curve with no

FIGURE 22-3. Theoretical insulin biologic action dose-response curves. **A.** Binding defect (this includes decreased insulin binding and/or decreased coupling of insulin binding to biologic responses). **B.** Isolated postbinding defects. **C.** A combined binding and postbinding defect.

change in maximal insulin action, and this is termed a *decrease in insulin sensitivity* (Fig. 22-3A). Certain kinds of postbinding defects involving the coupling mechanisms can also lead to rightward-shifted dose-response curves, leading to decreased insulin sensitivity.

2. A pure postreceptor defect in insulin action usually leads to a proportionate reduction in biological effects at all insulin concentrations. This is termed a *decrease in insulin responsiveness* (Fig. 22-3B).
3. If both a receptor and a postreceptor defect coexist, the dose-response curve shifts to the right and maximal insulin responsiveness decreases (Fig. 22-3C).

Hereafter, the terms *decreased insulin sensitivity* and *decreased insulin responsiveness* will be used in relation to the concepts depicted in Fig. 22-3.⁸⁷ One caveat when applying these concepts to *in vivo* insulin action is important to keep in mind: the heterogeneous nature of the system under study *in vivo*.

IN VIVO INSULIN RESISTANCE IN T2DM AND OBESITY

Type 2 Diabetes

Pathogenesis and Etiology

Before beginning a detailed discussion of the insulin resistance in T2DM, it is useful to put this metabolic defect into perspective by examining the overall pathophysiology of this disease. Figure 22-4 summarizes the physiologic abnormalities commonly seen in patients with T2DM. Although this is a genetically heterogeneous disease, once the diabetic syndrome is fully manifest, there is a final common metabolic pathway for the pathogenesis of hyperglycemia which involves defects in the liver, in the pancreatic islets, and in peripheral target tissues, particularly skeletal muscle.⁸⁸⁻⁹¹ As shown in Fig. 22-4, increased basal hepatic glucose production is characteristic of essentially all type 2 diabetic patients with fasting hyperglycemia.^{88,92-94} Skeletal muscle is depicted as the prototypical peripheral insulin target tissue, because in the *in vivo* insulin-stimulated state, 70–80% of all glucose uptake is into skeletal muscle. Target tissues are insulin resistant in T2DM, and this is a characteristic feature of this disease, seen in essentially all population groups studied. Lastly, abnormal islet cell function plays a central role in the eventual development of hyperglycemia in T2DM; decreased β -cell function and increased glucagon secretion are also frequently present in the diabetic state. Taken together, abnormalities in these three organ systems account for the full-blown syndrome of T2DM.

Figure 22-4 represents a pathophysiologic view at a single point in time after overt type 2 diabetes has developed. However, such a description does not provide insight into the natural history of the disease. The disorder is progressive, evolving in stages, as depicted in Fig. 22-5. Whether or not the insulin resistance of T2DM is a primary or a secondary phenomenon has been the subject of intense study in recent years. To answer this question,

FIGURE 22-4. Summary of the metabolic abnormalities in type 2 diabetes mellitus (T2DM) that contribute to hyperglycemia. Increased hepatic glucose production, impaired insulin secretion, and insulin resistance due to receptor and postreceptor defects all combine to generate the hyperglycemic state.

CAUSES OF HYPERGLYCEMIA IN NIDDM

various prediabetic populations have been examined prospectively.⁹⁵⁻⁹⁸ In these studies, conducted in a wide variety of populations, it has been reported that insulin resistance and hyperinsulinemia exist in the prediabetic state, many years before T2 supervenes. At this stage, insulin secretion in response to intravenous glucose is also often increased.^{95,97-99} Thus, while acquired factors, such as obesity and a sedentary lifestyle, may be additive, insulin resistance is likely to be a primary inherited component of the disease in most patients. In the presence of primary insulin resistance, if β -cell function is normal, hyperinsulinemia ensues to maintain maintenance of relatively normal glucose homeostasis. Impaired glucose tolerance (IGT) eventually develops in a subpopulation of individuals with compensated insulin resistance. Those with IGT also typically have fasting and postprandial hyperinsulinemia, but this is not sufficient to fully compensate for insulin resistance. This may be because they have a more profound degree of insulin resistance or because of a limited ability to augment their insulin secretion rates.¹⁰⁰ Although some subjects with IGT may revert to normal glucose tolerance, many will progress to overt T2DM. The proportion of insulin-resistant subjects who progress to T2DM depends on the particular ethnic group studied. In most populations, the rate of progression of IGT to type 2 diabetes is 2–6% per year over 10 years.¹⁰¹ Those who progress to T2DM display a marked decline in insulin secretion. The etiology of this decrease in β -cell function is not known. It may result from preprogrammed genetic abnormalities and/or from acquired insults such as those caused by the chronic effects of mild hyperglycemia or elevated FFAs/levels, commonly referred to as glucotoxicity and lipotoxicity.

FIGURE 22-5. Proposed etiology for the development of type 2 diabetes mellitus. HGO = hepatic glucose output.

respectively. It could also result from an inherited susceptibility to the effects of chronic hyperglycemia or elevated FFA levels. Regardless of the etiology, this decrease in insulin secretion is a major contributor to the development of the overt type 2 diabetic state.

The contribution of genetics to the etiology of T2DM is well accepted,¹⁰² and is demonstrated by studies showing a greater than 90% concordance rate for T2DM in identical twins.¹⁰³ In addition, the incidence of T2DM is much higher in individuals with first-degree relatives with the disease.¹⁰⁴ Given this strong genetic component to T2DM and that insulin resistance predates the development of T2DM in most populations, it is likely that insulin resistance is an inherited initial lesion in most patients. However, considerable data also exist that indicate that the magnitude of the insulin resistance is greater in T2DM than it is in the prediabetic IGT state. Although not all reports agree with this conclusion, most do. For example, Eriksson and colleagues showed that offspring of type 2 diabetic parents are insulin resistant.⁹⁶ When they divided the cohort of offspring into weight- and age-matched groups with normal glucose tolerance (NGT), IGT, and T2DM, they found that the hyperglycemic diabetic offspring were more insulin resistant than the NGT or IGT groups. Perhaps more compelling is the work by Vaag and associates, who studied monozygotic twins in which only one twin had T2DM.¹⁰⁵ They found that the nondiabetic twins were insulin resistant compared to matched controls, but that the diabetic twins were considerably more insulin resistant. Obviously, these subjects were well matched for genetic influences as well as other factors. These studies are quite consistent with population-based results showing that type 2 diabetic subjects are more insulin resistant than those with IGT.⁹³ Thus one can propose that once T2DM develops, some factor creates a secondary component of insulin resistance that is additive to the component that existed in the prediabetic state. There is strong evidence that hyperglycemia *per se* plays a role and that elevated glucose levels can cause insulin resistance or exacerbate an underlying insulin-resistant state.^{106,107}

For example, poorly controlled type 1 diabetic patients are insulin resistant,^{106,108} as are alloxan diabetic dogs¹⁰⁹ and pancreatectomized diabetic rats.¹¹⁰ The insulin resistance in recently diagnosed type 1 diabetic patients is completely reversed by intensive insulin therapy,^{106,108} and in pancreatectomized diabetic rats it is normalized by controlling the hyperglycemia via phlorhizin-mediated renal glycosuria.¹¹⁰ In more direct experiments, when well-controlled type 1 diabetic patients were infused with glucose, whole-body insulin sensitivity, forearm glucose uptake, and muscle glycogen deposition were all reduced by approximately 35% after blood glucose had been maintained at 20 mmol/L (360 mg/dL) for a period of 24 hours.¹¹¹ In specific regard to T2DM, it has been shown that tight glycemic control achieved by intensive insulin therapy improves peripheral tissue insulin sensitivity by 17–75% in various studies.^{107,112,113} Other forms of treatment which improve glycemia are also associated with partial restoration of insulin sensitivity in T2DM.^{78,107,114–116} The most likely cause of this reversible component of insulin resistance is hyperglycemia-mediated glucotoxicity, although other factors associated with the poorly controlled hyperglycemic state such as elevated FFA levels may also play a role.

From the foregoing it can be concluded that in established T2DM there are two components to insulin resistance. The first is a primary, probably inherited abnormality, and the second is an acquired component, most likely due to hyperglycemia-related toxicity. In this way, a vicious cycle is created in which hyperglycemia begets more hyperglycemia.

As discussed above, insulin resistance is also a characteristic feature of subjects with IGT.^{76,88–90} In general, subjects with IGT have less severe insulin resistance than patients with overt T2DM.^{76,77,96,105} Furthermore, as the degree of carbohydrate intolerance worsens, the frequency of insulin resistance increases.⁷⁷ Thus many, but not all, subjects with IGT are insulin resistant, while essentially every type 2 diabetic patient with significant fasting hyperglycemia displays this abnormality. Obesity, particularly when it is centrally distributed, is a well-known condition also associated with insulin resistance. Since most adult type 2 diabetic patients are overweight, obesity-induced insulin resistance is thought to be a contributing factor in the hyperglycemia of these patients. However, obesity does not account for all of the insulin resistance in this type of diabetic patient, since the insulin resistance exceeds that caused by obesity alone, and nonobese type 2 diabetic patients are also insulin resistant.^{88–90,117}

In Vivo Studies of Insulin Sensitivity

All methods of assessing insulin action *in vivo* rely, in one way or another, on measurement of the ability of a fixed dose or concentration of insulin to promote glucose disposal. Thus a blunted decline in the plasma glucose concentration following intravenous insulin in T2DM has been demonstrated.^{117,118} One approach to quantifying insulin sensitivity has been to infuse insulin and glucose at fixed rates while endogenous insulin secretion is inhibited by either a combination of epinephrine and propranolol, or by somatostatin.^{117,119,120} With this method, the resulting steady-state plasma glucose level reflects the action of the concomitantly infused insulin; the higher the steady-state plasma glucose, the greater the degree of insulin resistance.¹¹⁷ Another method of assessing insulin sensitivity is the “minimal model” developed by Bergman and colleagues,¹¹⁷ in which the plasma glucose and insulin levels following an intravenous glucose bolus are fed into a mathematical model to generate an index of insulin sensitivity (S_i). The test was adapted for type 2 diabetic patients with poor insulin secretion by giving an injection of insulin 20 minutes after the glucose bolus. With all these methods, significant insulin resistance has been demonstrated in the overwhelming majority of type 2 diabetic patients.

The site of this resistance to insulin-stimulated glucose disposal is primarily at the level of skeletal muscle. Thus, forearm and leg glucose balance studies have shown that 80–85% of overall *in vivo* insulin-mediated glucose uptake is accounted for by skeletal muscle, and that skeletal muscle is markedly resistant to insulin's ability to stimulate glucose uptake in T2DM.^{121–123}

More detailed *in vivo* studies of insulin sensitivity have been carried out using the euglycemic glucose clamp method developed by Andres and colleagues.^{117,124} With this approach, insulin is infused at a constant rate to maintain a given steady-state plasma insulin level. At the same time, the plasma glucose level is frequently monitored and hypoglycemia is prevented by infusing glucose at a variable rate, which is periodically adjusted to maintain a constant plasma glucose level. The amount of glucose that has to be infused to keep plasma glucose constant increases gradually until a steady state is reached. If a radioactive or stable isotope of glucose is also infused during the study, the rate of hepatic glucose output during the clamp can be quantified. At steady state, the isotopically measured rate of glucose disposal provides an excellent quantitative assessment of the biological effect of a particular steady-state insulin concentration. If several studies at different insulin levels are performed in a given subject, the dose-response curve for insulin-

FIGURE 22-6. Mean steady-state glucose disposal rates (right panel) and plasma insulin levels (left panel) for control subjects, nonobese subjects with impaired glucose tolerance, and type 2 diabetic patients (T2DM) during euglycemic glucose clamp studies performed at an insulin infusion rate of $40 \text{ mU/m}^2/\text{min}$. Results are plotted as means $\pm$ SEM.

stimulated glucose disposal and suppression of hepatic glucose output can be constructed. The steady-state glucose disposal data from such a glucose clamp study, in which a submaximally stimulating insulin infusion rate was used in normal, nonobese IGT subjects and obese or nonobese type 2 diabetic subjects, are shown in Fig. 22-6.⁹³ As can be seen, steady-state insulin levels were comparable in all subjects, but the glucose disposal rates were decreased in the patient groups and the magnitude of this defect was greatest in the patients with the worst carbohydrate intolerance.

To further explore the mechanisms of this insulin resistance, the *in vivo* dose-response relationship was examined by performing additional euglycemic glucose clamp studies at insulin infusion rates of 40, 120, 240, or $1200 \text{ mU/m}^2/\text{min}$.⁹³ As seen in Fig. 22-7, the subjects with IGT had a rightward shift in their dose-response curves (diminished sensitivity), but their maximal rate of glucose disposal was not significantly different from that of the control sub-

jects, indicating normal insulin responsiveness. The patients with T2DM (obese and nonobese) exhibited both a rightward shift in their dose-response curves and a marked decrease in the maximal rate of glucose disposal. These changes tended to be more pronounced in the obese diabetic patients, especially at the highest insulin concentration. Clearly, the predominant lesion responsible for the insulin-resistant state in the patients with fasting hyperglycemia appears to be a postbinding defect in insulin action, leading to a marked decrease in maximal insulin responsiveness. This abnormality is present in both nonobese and obese T2DM patients showing that this postbinding defect in insulin action is not simply a result of obesity.

Inspection of the individual data in the type 2 diabetic patients showed that the patients with the lower fasting glucose levels were less insulin resistant and had the smallest reductions in maximal glucose disposal rates (Fig. 22-8), which suggests that the degree of the postbinding defect is greater as the severity of the diabetic state increases. Clearly, this is consistent with the concept discussed earlier that there is a primary and an acquired component to the insulin resistance in T2DM, and that the acquired component may be secondary to the development of chronic hyperglycemia.

FIGURE 22-7. Mean insulin dose-response curves for glucose disposal in control subjects ($\bullet$), subjects with impaired glucose tolerance ($\circ$), and nonobese (Δ) and obese ($\blacktriangle$) type 2 diabetic subjects.

Hepatic Glucose Metabolism

The liver is capable of extracting glucose from the blood delivered via portal vein and hepatic artery as well as releasing glucose derived from glycogenolysis or gluconeogenesis into the hepatic vein.

Hepatic Glucose Production

After an overnight fast, about 90% of the glucose released into the circulation comes from the liver. In normal subjects, basal glucose production rates are around $1.8\text{--}2.2 \text{ mg/kg/min}$. After carbohydrate ingestion, hepatic glucose output (HGO) falls and this helps to limit the rise in plasma glucose levels. As intestinal delivery of glucose wanes, basal HGO rates must be restored to prevent hypoglycemia. These changes in HGO are largely mediated by changes in insulin and other hormones that oppose insulin's effects on hepatic gluconeogenesis and glycogenolysis through alterations in the supply of gluconeogenic substrate, and by the effects of the hepatic plasma glucose concentration *per se*.

FIGURE 22-8. Relationship between fasting serum glucose level and maximal glucose disposal rate in individual subjects with IGT ($\circ$) and nonobese ($\blacktriangle$) and obese ($\blacksquare$) type 2 diabetes.

HGO is abnormal in T2DM.^{92-94,112,115} The basal rate of HGO is increased, whether or not the diabetic patients are obese, but is normal in subjects with IGT (Fig. 22-9A). The importance of this abnormality in sustaining the hyperglycemic state is best illustrated by examining the relationship between HGO and the fasting plasma glucose level in individual subjects. Figure 22-9B illustrates the very close correlation between these two variables, indicating that it is the rate of glucose production by the liver that appears to be most directly responsible for the level of fasting hyperglycemia in T2DM.

Most studies suggest that gluconeogenesis is increased in T2DM and that this is the proximate cause of their increased HGO.¹²⁵⁻¹²⁷ However, the exact mechanisms remain unclear, and it is likely that the abnormalities of gluconeogenesis and HGO are multifactorial in origin. Glucagon levels are elevated in T2DM (see Chap. 7), and the effect of glucagon to stimulate the synthesis and release of glucose by the liver is well known. Hyperglycemia normally exerts a potent suppressive effect on α -cell glucagon secretion, and the presence of hyperglucagonemia in the face of hyperglycemia is consistent with the view that pancreatic α cells are resistant to the inhibitory effects of glucose in type 2 diabetic subjects. Insulin also normally suppresses glucagon secretion, and this may reflect an intraislet paracrine function of β -cell insulin secretion inhibiting α -cell glucagon release.¹²⁸ This effect is also possibly impaired in T2DM. Other factors could be at work, but regardless of the mechanisms, increased α -cell function in T2DM is an important and consistent abnormality. If somatostatin is infused to induce isolated glucagonopenia, it can be demonstrated that about two-thirds of basal HGO is glucagon dependent in normal and type 2 diabetic subjects.^{129,130}

Hepatic glucose production can be completely suppressed by high physiologic or supraphysiologic insulin levels in T2DM, but there is resistance to suppression of HGO at lower insulin concentrations.^{131,132} This hepatic insulin resistance also likely contributes to exaggerated glucose production rates in this condition. Because insulin's effect on HGO may in part be indirect and mediated by suppression of adipose tissue lipolysis and plasma FFA levels,¹³³ it is possible that the defect of HGO suppression in T2DM may in part be secondary to impaired suppression of plasma FFA levels by

FIGURE 22-9. A. Rates of hepatic glucose output (HGO) in the basal state (7 to 9 AM following an overnight fast) in normal subjects, subjects with IGT, and obese or nonobese subjects with type 2 diabetes. HGO is normal in patients with IGT but is increased in type 2 diabetes. B. Relationship between hepatic glucose production rates and fasting serum glucose levels in type 2 diabetic subjects.

A

B

insulin.^{131,133–135} However, resistance to insulin's direct effects on HGO is undoubtedly also present in T2DM.¹³⁶

Finally, the increased flux of the gluconeogenic precursors lactate, alanine, and glycerol from peripheral tissues to the liver may participate in the maintenance of the increased rate of HGO in T2DM.¹³⁷ The finding that plasma alanine levels are usually normal in T2DM despite increased entry of alanine into the circulation¹²⁶ is consistent with an increased uptake of alanine by the liver. The substrate-induced increase in HGO could be at least partly related to differences in intracellular disposition of glucose in peripheral target tissues in normal versus insulin-resistant type 2 diabetic subjects. In the basal state, Ra (the rate of glucose appearance) is increased in hyperglycemic type 2 diabetic patients because of increased HGO, and under the near steady-state conditions that exist in the basal state this means that total glucose disposal (Rd) is also elevated. When basal tissue glucose uptake is enhanced by hyperglycemia in diabetes, the proportion of glucose metabolized by glycolysis to lactate and pyruvate tends to be increased.¹³⁸ Some of the pyruvate is converted to alanine by transamination and these three-carbon compounds can be recycled to the liver (Cori cycle) to be reconverted to glucose, facilitating increased HGO. Consistent with this formulation, increased flow of three-carbon precursors from muscle in the basal state and their reincorporation into glucose has been described in T2DM.^{126,127} The increased FFA levels generally observed in hyperglycemic diabetic subjects could provide the energy, via fatty acid oxidation, to drive the increased rate of hepatic gluconeogenesis.

Hepatic Glucose Uptake

Although earlier data held that the majority of orally ingested glucose was extracted by the liver and largely converted to glycogen,¹³⁹ more recent studies suggest that only 20–35% of oral glucose is directly taken up (as glucose) by the liver, and even less (about 10%) of the glucose absorbed from the gut is taken up on first pass.¹⁴⁰ Thus the majority of the incoming glucose load enters the peripheral circulation and skeletal muscle is quantitatively the predominant site of glucose disposal.¹⁴¹ Taylor and colleagues, using ¹³CNMR spectroscopy to quantitate liver glycogen in normal subjects, estimated that only 19% of the carbohydrate content of a liquid meal consumed after an overnight fast was incorporated into liver glycogen.¹⁴² Furthermore, much of the liver glycogen is derived through the indirect pathway from incoming amino acids, lactate, and pyruvate via gluconeogenesis (more properly glycogenesis) rather than directly from glucose.^{141–143} Insulin does not directly stimulate hepatic glucose uptake; it plays a permissive role. An increase in the portal venous glucose concentration and the establishment of a positive portal–arterial glucose gradient is a prerequisite for net hepatic glucose uptake;^{144,145} under these circumstances insulin will augment the net uptake of glucose by the liver.¹⁴⁵ After glucose ingestion, uptake of glucose by the liver (newly absorbed and recirculating) is impaired in T2DM.¹⁴⁶ A recent study found that in patients with T2DM, splanchnic glucose uptake during combined hyperinsulinemia and hyperglycemia was impaired, as was the incorporation of glucose into hepatic glycogen by the direct pathway, whereas hepatic glycogen synthesis via the indirect pathway from three-carbon intermediates was not significantly decreased.¹³²

In summary, in T2DM the liver overproduces glucose in the basal state and the metabolic milieu is ideal to sustain this ability. Exaggerated hormonal stimulation is provided by the increased glucagon levels in combination with hepatic insulin resistance, and

augmented gluconeogenic precursor flow ensures adequate substrate availability. Finally, elevated FFA levels could provide necessary source of intracellular energy, via fatty acid oxidation drive the gluconeogenic process. Postprandially, suppression HGO and uptake of glucose by the liver are impaired in T2DM; these defects contribute to postprandial hyperglycemia.

Insulin-Mediated versus Non-Insulin-Mediated Glucose Uptake and the Pathogenesis of Hyperglycemia

Overall glucose uptake can be conveniently divided into non-insulin-mediated glucose uptake (NIMGU) and insulin-mediated glucose uptake (IMGU) (Fig. 22-10). Because of the difference in the relative proportions of insulin-mediated and non-insulin-mediated glucose uptake with fasting and feeding, the cause of fasting hyperglycemia is different from the cause of postprandial hyperglycemia. By definition, IMGU occurs only in insulin target tissues under the influence of insulin. NIMGU comprises glucose uptake not under the influence of insulin and has two components. NIMGU occurs in tissues (primarily the central nervous system) that are not targets for insulin action; it also involves insulin target cells and consists of the basal rate (non-insulin-mediated) of glucose disposal (Rd) by these tissues. Total glucose Rd equals the sum of NIMGU plus IMGU (Fig. 22-10). NIMGU can be assessed *in vivo* by measuring glucose Rd under conditions of severe insulinopenia induced by an infusion of somatostatin.^{147,148} Following measurement of basal glucose Rd (at basal or fasting insulin and glucose levels), somatostatin is administered to inhibit insulin secretion to negligible levels. Glucose Rd gradually falls to a new steady state that equals NIMGU, because insulin action is nearly absent under these conditions. Using this method, approximately 70% of basal glucose Rd is non-insulin-mediated in normal euglycemic subjects and in type 2 diabetic subjects studied at their basal level of hyperglycemia.¹⁴⁷ This means that in the basal state at all levels of glycemia, most of the glucose is disposed of by non-insulin-mediated mechanisms, and that the elevated rates of basal glucose Rd (due to an increased HGO) that prevail in T2DM are associated with increased rates of NIMGU.

How does this consideration of non-insulin-mediated and insulin-mediated glucose uptake relate to the cause of fasting hyperglycemia? This is summarized in Table 22-2. Because IMGU comprises only 30% of basal glucose Rd, it follows that an impairment of IMGU due to insulin resistance and/or decreased insulin secretion will have little effect on overall basal glucose Rd or

FIGURE 22-10. Overall basal glucose uptake divided into its constituent parts. Most non-insulin-mediated glucose uptake occurs in the central nervous system.

TABLE 22-2. Etiology of Fasting versus Postprandial Hyperglycemia**Basal State**

1. Non-insulin-mediated glucose uptake predominates (70% of basal glucose disposal)
2. Glucose output (hepatic glucose production) equals glucose disposal (insulin-mediated glucose uptake plus non-insulin-mediated glucose uptake) equals 2 mg/kg/min
3. Non-insulin-mediated glucose uptake equals 1.4, and insulin-mediated glucose uptake equals 0.6 mg/kg/min
4. A 50% decrease in insulin-mediated glucose uptake equals a 15% decrease in glucose disposal to 1.7 mg/kg/min
5. Fasting blood glucose (85 mg/dL) increases to about 100 mg/dL, and glucose disposal increases 15%, back to 2.0 mg/kg/min
6. If glucose output increases from 2.0 to 2.6 mg/kg/min, then insulin-mediated glucose uptake must increase from 0.6 to 1.2 mg/kg/min to prevent hyperglycemia
7. This requires a five- to sixfold increase in insulin level, which cannot be readily achieved in type 2 diabetes mellitus
8. Fasting hyperglycemia is largely secondary to increased glucose output (hepatic glucose production)

Postprandial State

1. Insulin-mediated glucose uptake predominates (80–90% of glucose disposal)
2. Postprandial glucose disposal increases to 7 mg/kg/min
3. Non-insulin-mediated glucose uptake then equals 1.4, and insulin-mediated glucose uptake equals 5.6 mg/kg/min
4. A 50% decrease in insulin-mediated glucose uptake leads to a 40% decrease in glucose disposal
5. Postprandial hyperglycemia is largely secondary to a restricted rise in insulin-mediated glucose uptake

fasting glucose levels. For example, if a normal basal rate of glucose Rd is 2 mg/kg/min and IMGU is equal to 0.6 mg/kg/min (30%), then a 50% decrease in IMGU will lower glucose Rd by 0.3 mg/kg/min, a 15% reduction. A slight (about 15%) rise in plasma glucose level is all that is necessary to provide a sufficient mass action effect of glucose to restore glucose Rd back to the original level. Thus the restriction of IMGU in type 2 diabetes is not the proximate cause of fasting hyperglycemia. Because the fasting glucose level reflects the balance between glucose output and glucose Rd, then if reduced glucose Rd does not lead to significant fasting hyperglycemia, it follows that increased glucose entry into the circulation (essentially HGO) is the factor most directly responsible for fasting hyperglycemia. This is because in the setting of peripheral insulin resistance and impaired insulin secretion, the ability of IMGU to rise and accommodate an increase in glucose output is severely curtailed. Thus, using the above example (Table 22-2), if basal HGO and glucose Rd are 2 mg/kg/min at euglycemia, with IMGU accounting for only 30% of glucose Rd, then a modest increase in HGO to 2.6 mg/kg/min would require a doubling of IMGU (from 0.6 to 1.2 mg/kg/min) to maintain glucose Rd equal to the new HGO with no change in basal glucose level.

A normal subject can increase basal IMGU twofold with less than a twofold increase in plasma insulin above the basal concentration. Thus, with a normal ability to secrete insulin and a normal capacity of peripheral tissues to respond to insulin, a control subject can easily accommodate a rise in glucose output from 2.0 to 2.6 mg/kg/min with little if any change in fasting glucose level. In T2DM, the situation is quite different; a five- to sixfold increase in plasma insulin is necessary to increase IMGU twofold over the basal value. Thus, because of insulin resistance, type 2 diabetic

subjects need much larger increases in plasma insulin to increase IMGU, and in view of their impaired insulin secretion, this is unlikely to be achieved. Therefore, the fasting glucose level must rise until the mass action effect of glucose raises glucose Rd sufficiently to match the increased glucose output and thus bring the system back into balance. At this point increased glucose output is matched by increased glucose Rd in the presence of fasting hyperglycemia. Thus, in T2DM, the inability to augment IMGU due to the presence of insulin resistance and restricted insulin secretion provides the metabolic foundation that allows relatively small increases in glucose output (HGO) to cause direct and proportionate increases in the fasting glucose level.⁹²

The cause of postprandial hyperglycemia is quite different (Table 22-2). The majority of ingested glucose bypasses the liver and enters the peripheral circulation.¹⁴⁰ This is accompanied by rapid suppression (60–90%) of HGO for 2–3 hours after carbohydrate ingestion.^{138,140,142} Therefore, in the postprandial state, the main source of glucose appearing in the circulation is the ingested carbohydrate. Glucose absorbed from the gut largely enters the systemic circulation to be disposed of mostly by skeletal muscle through a severalfold increase in IMGU. Since IMGU can make up 80–90% of overall glucose disposal, decreases in IMGU due to insulin resistance and insulin deficiency will markedly reduce glucose disposal at any given glucose level. In T2DM, systemic delivery of ingested glucose appears to be normal, but suppression of HGO is impaired as a result of insulin resistance and impaired insulin secretion,¹³⁸ which means that the total quantity of glucose appearing in the circulation is somewhat higher. In addition, the efficiency of peripheral glucose removal is greatly reduced because of insulin resistance and impaired insulin secretion. Hepatic uptake of glucose (newly absorbed plus recirculating) is also impaired in T2DM.^{138,146} Thus, postprandial hyperglycemia in T2DM is primarily due to impaired IMGU by peripheral tissues, with impaired suppression of HGO and impaired hepatic glucose uptake compounding the problem. Because of the very limited capacity for an acute increase in IMGU, postprandial glucose levels must rise markedly until the mass action effect of glucose raises glucose Rd to match glucose input and allow disposal of the incoming glucose load.

In summary, in the basal state, NIMGU predominates, and decreased IMGU will raise fasting blood glucose levels only modestly. Fasting hyperglycemia is primarily due to increased hepatic glucose production. In the postprandial state, IMGU normally predominates, and the limited ability of type 2 diabetic subjects to increase IMGU allows the marked postprandial glucose excursions. Postprandial hyperglycemia is thus primarily due to glucose underutilization by peripheral tissues (primarily muscle).

Obesity

Insulin resistance has been widely described in human obesity, and this has been documented by observing an attenuated ability of exogenous insulin to promote glucose disposal using a variety of techniques. These range from measurements of hypoglycemic responses to bolus insulin injections,¹⁴⁹ forearm perfusions,⁶ and glucose clamp studies.^{88,124,150} Using the euglycemic clamp technique over a range of insulin infusion rates to construct individual insulin dose–response curves for *in vivo* glucose disposal and HGO (as discussed earlier), a rightward shift in the dose–response curve for insulin-stimulated glucose disposal is a consistent finding in obese subjects. However, the response to a maximally stimulating insulin concentration is quite variable, covering the whole spectrum from

normal to markedly reduced.¹⁵⁰ Figure 22-11 shows the mean insulin dose-response curves obtained in a group of normal and obese subjects. Some of the obese subjects achieved a normal or near-normal maximal insulin stimulated glucose disposal rate, whereas others displayed a markedly decreased maximal glucose disposal rate. In the figure, the obese subjects have been arbitrarily divided into two groups: (1) those showing a normal maximal rate of insulin-stimulated glucose disposal (group I obese) and (2) those displaying a markedly decreased maximal glucose disposal rate (group II obese). With this analysis, the insulin resistance associated with obesity is heterogeneous; some patients display only a rightward shift in the dose-response curve, consistent with decreased insulin binding as the sole abnormality (decreased insulin sensitivity), while others show a decreased maximal response, consistent with a postbinding defect in insulin action (decreased insulin responsiveness). Indeed, there are several reports of postbinding defects in insulin signaling in muscle and adipocytes from obese subjects.

It is apparent that the patients with normal maximal rates of glucose disposal are less insulin resistant. They also are less hyperinsulinemic and have a smaller reduction in insulin receptors than the subjects with reduced maximal responsiveness (Fig. 22-12). Although all of the subjects were hyperinsulinemic and insulin resistant, the data suggest that no postbinding defect exists in the least affected subjects. The findings indicate a continuum of insulin resistance in human obesity such that in the mildly hyperinsulinemic,

insulin-resistant state, only a binding defect exists; however, as the hyperinsulinemic, insulin-resistant state worsens, a postbinding defect appears.

Hepatic glucose output (HGO) was measured during all studies and these results are plotted in Fig. 22-13. Basal HGO was comparable for all groups when expressed as $\text{mg}/\text{m}^2/\text{min}$ (66 ± 5 , 63 ± 4 , and 67 ± 5 $\text{mg}/\text{m}^2/\text{min}$ for control, group I obese, and group II obese, respectively), but was significantly higher for the normal subjects when expressed on a per kilogram basis (2.0 ± 0.2 $\text{mg}/\text{kg}/\text{min}$ versus 1.4 ± 0.1 and 1.3 ± 0.1 $\text{mg}/\text{kg}/\text{min}$ for the group I obese and group II obese, respectively). Several conclusions can be drawn from the data in Fig. 22-13. First, HGO can be totally suppressed in all subjects, provided high enough insulin concentrations are employed. Thus, in contrast to insulin's effects on peripheral glucose disposal, the liver of obese subjects does not appear to exhibit a postbinding defect in this insulin effect. Second, the dose-response curves for HGO are shifted to the right in the obese groups, and the half-maximally effective insulin levels were 33, 75, and 130 mU/L in normal, group I obese, and group II obese subjects, respectively. This parallels the results for peripheral glucose disposal.

A number of factors, including the habitual physical activity level¹⁵¹ and the regional distribution of body fat,¹⁵²⁻¹⁵⁵ could contribute to the heterogeneity of insulin resistance in human obesity. Overweight individuals tend to be sedentary. Bogardus and associates¹⁵¹ found that the level of habitual physical activity (estimated by measurement of maximal oxygen consumption) accounted for about 25% of the variance in insulin-mediated glucose disposal in normal subjects over a wide range of body mass indices. It follows that the habitual physical activity level of obese subjects participating in studies of insulin action could be one determinant of whether they have a decrease in maximal responsiveness or only a rightward shift in their insulin dose-response curve.

Several studies suggest that obese subjects with a predominantly central (abdominal/truncal) distribution of body fat are more insulin resistant and have higher circulating insulin levels than those with peripheral obesity, independent of the overall degree of

FIGURE 22-11. Dose-response curves for *in vivo* glucose disposal in control subjects (●), and obese subjects separated into two groups on the basis of their maximal response: group I (○) and group II (▲) (see text for details). Results were obtained by performing euglycemic clamp studies in each subject with insulin infusion rates of 15, 40, 120, 240, or 1200 $\text{mU}/\text{m}^2/\text{min}$. The initial point on the curve represents glucose disposal in the basal state as measured by a primed continuous infusion of 3-3H-glucose. Data are presented as mean $\pm$ SEM.

FIGURE 22-12. Insulin binding by isolated adipocytes from control (●), group I (○), and group II (▲) obese subjects. All data are corrected for non-specific binding and represent the mean ($\pm$ SEM) percentage of ^{125}I -insulin specifically bound/ 2×10^5 cells.

FIGURE 22-13. Mean dose-response curves for insulin-mediated suppression of basal hepatic glucose output for control (●), group I (○), and group II (▲) obese subjects.

obesity.¹⁵²⁻¹⁵⁵ In contrast, total body fat content rather than its distribution is an important determinant of insulin sensitivity in mildly obese subjects. Once an individual exceeds 25-30% of ideal body weight ($\text{BMI} > 27 \text{ kg/m}^2$), further increases in total fat mass have relatively little additional influence on insulin sensitivity, and the distribution of fat (i.e., central versus peripheral) assumes greater importance as a determinant of insulin action and circulating insulin levels.^{153,155,156} Therefore, a more central distribution of body fat could be a determinant of whether obese subjects exhibit a decrease in maximal insulin responsiveness.

The prevailing view is that the adverse metabolic effects associated with central obesity are due to the accumulation of visceral fat, which is lipolytically more active.^{157,158} FFAs may impair hepatocyte insulin receptor function,¹⁵⁹ and if so, this would cause decreased hepatic insulin clearance in subjects with central obesity.¹⁶⁰ High circulating insulin levels may desensitize the target tissues at several steps in the insulin action sequence. This raises the possibility that the hyperinsulinemia in subjects with central abdominal obesity may cause a decrease in maximal insulin responsiveness. This formulation fits with the observation that a decrease in maximal insulin responsiveness is seen in the most hyperinsulinemic obese subjects, and that the magnitude of the defect is directly related to the degree of hyperinsulinemia.

CELLULAR DEFECTS IN INSULIN ACTION

From the foregoing discussion, it is likely that in obese or type 2 diabetic patients with mild degrees of insulin resistance, the defect is characterized by decreased insulin sensitivity, which may be attributable, at least in part, to a decreased number of insulin receptors. In those subjects with more severe insulin resistance, a postbinding defect in cellular insulin action is the predominant abnormality. A great deal of recent attention has been paid to elucidating potential postbinding abnormalities in insulin action in tissues from type 2 diabetic and obese subjects.

Insulin Binding

As discussed earlier, a large number of studies have found that insulin binding to a variety of tissues is decreased in type 2 diabetic patients relative to controls, and many studies, but not all, have also

shown a decrement in obese patients.^{74-79,93,150,161,162} Using partially purified adipocyte insulin receptors, it was found that at all concentrations of added insulin, the amount of insulin bound was 20% lower in obese subjects and nearly 50% less per milligram of protein in the obese diabetics relative to lean controls.¹⁵⁰

Insulin-Stimulated Autophosphorylation

The first known event following insulin binding to its receptor is activation of the tyrosine kinase property intrinsic to the cytoplasmic domain of the β subunit. For functional studies of receptor kinase activity, receptors can be partially purified from cells by affinity chromatography using the lectin wheat germ agglutinin to adsorb the receptors from solubilized cells. When wheat germ-purified receptors were preincubated with increasing concentrations of insulin, and then exposed to $[\gamma\text{-}^{32}\text{P}]\text{ATP}$, there was an insulin-dependent increase in the amount of ^{32}P incorporated into the $\sim 92,000$ MW β subunit, as shown in Fig. 22-14A for a control subject. When the bands corresponding to the β subunit were excised and counted, a dose-response curve for insulin stimulation of autophosphorylation was constructed for subjects, as shown in Fig. 22-14B.

Figure 22-15 illustrates the dose-response curves for autophosphorylation of adipocyte insulin receptors in control, obese, and type 2 diabetic subjects.¹⁶² In the absence of insulin, basal autophosphorylation was not significantly different among the three groups (control, 1.73 ± 0.24 ; obese, 1.65 ± 0.28 ; type 2 diabetic, 1.47 ± 0.37 fmol phosphate/76 fmol insulin-binding activity), and the basal level was subtracted from all corresponding values measured in the presence of different concentrations of insulin. Analyzed in this manner, the results displayed in Fig. 22-16 reflect only insulin-stimulated autophosphorylation. When equal amounts of insulin receptors were allowed to autophosphorylate, the amount of phosphate incorporated into the β subunit of the receptor was similar in the lean controls and nondiabetic obese subjects at all insulin concentrations. In contrast, the amount of autophosphorylation was markedly reduced ($p < 0.01$) in the type 2 diabetic subjects relative to the two other groups.

As previously discussed, skeletal muscle represents the major insulin target tissue with respect to insulin-stimulated glucose disposal, and therefore it is important to examine insulin receptor kinase activity in this tissue. To accomplish this, the kinase activity

FIGURE 22-14. Dose-response of autophosphorylation of insulin receptors from human adipocytes. Aliquots of wheat germ-purified receptors from three lean nondiabetic subjects were preincubated in the presence and absence of increasing concentrations of unlabeled insulin, with or without 0.5 ng/mL ^{125}I -insulin. After 18 hours at 4°C, autokinase and insulin-binding assays were performed. **A.** Representative autoradiograph of insulin-stimulated autophosphorylation from a control subject. **B.** The phosphorylated proteins corresponding to 92,000 MW were located by autoradiography, excised, and counted. The amount of phosphate incorporated into the 92-kD band, expressed as the percentage of the maximal effect achieved at 1000 ng/mL insulin, is plotted as a function of increasing concentrations of added insulin. **C.** Kinase data from **B** redrafted as a function of the fraction of total receptors occupied with insulin at each concentration of added insulin, as determined by Scatchard plots of the binding data.

of insulin receptors was measured during glucose clamp studies using a technique which determines the magnitude of receptor kinase activity as it existed in the *in vivo* situation stimulated by the exogenous insulin infusion.¹⁶³ With this approach, glucose clamp studies were performed at different insulin infusion rates, and skeletal muscle biopsies were performed 3 hours after each insulin infusion. Kinase activity is then assessed using receptors purified

from these biopsies, and this provides a measure of the ability of circulating insulin to stimulate skeletal muscle insulin receptor kinase activity *in vivo*. As shown in Fig. 22-16, the results are comparable to those observed in adipocytes, with decreased kinase activity in type 2 diabetic patients compared to lean and obese nondiabetic subjects.¹⁶³ Similar findings have been reported using insulin receptors from liver¹⁶⁴ and erythrocytes.¹⁶⁵

FIGURE 22-15. Insulin dose-response of autophosphorylation. Aliquots of receptor preparations (76 fmol of insulin-binding capacity/80 μL) were preincubated with 0, 2, 5, or 500 ng/mL insulin, after which autokinase reactions were conducted for 30 minutes at 4°C. For each subject, the amount of ^{32}P incorporated into the 92-kD band in the absence (basal) of insulin was subtracted from all corresponding values measured in the presence of insulin. The results are graphed as the mean ($\pm$ SEM) increase over basal from 10 control ($\bullet$), 13 obese (Δ), and 13 type 2 diabetic ($\circ$) subjects.

FIGURE 22-16. Dose-response stimulation of skeletal muscle insulin receptor phosphorylation of histone-2B *in vivo* during euglycemic clamp studies. The results represent the kinase activity (mean $\pm$ SEM) expressed as increment over the basal values for lean nondiabetics (■), obese nondiabetics (▨), and type 2 diabetic subjects (▩). Type 2 diabetic versus lean controls, $p = 0.01$; type 2 diabetic versus obese, $p < 0.05$; obese versus lean controls, $p = \text{NS}$ (by ANOVA).

The impaired receptor kinase activity seen in the type 2 diabetic subjects appears to be relatively specific for the hyperglycemic diabetic state since no decrease in kinase activity was observed in adipocyte-,¹⁶² erythrocyte-,¹⁶⁵ and skeletal muscle-derived¹⁶³ receptors prepared from insulin-resistant nondiabetic obese subjects compared to lean nondiabetic controls. This suggests that the insulin receptor kinase defect is a consequence of the diabetic state rather than a primary inherited cause of insulin-resistance, and several lines of evidence support this idea. First, molecular studies have shown that the sequence of the insulin receptor gene is normal in >99% of subjects with "garden variety" T2DM, demonstrating that the insulin receptor does not represent a diabetes susceptibility gene, except in a small fraction of patients.^{166,167} Second, when obese type 2 diabetic patients lose weight, hyperglycemia is markedly improved and this is associated with partial amelioration of insulin resistance and normalization of receptor kinase activity.⁷⁸ One can speculate that hyperglycemia, or some closely related factor, causes the receptor kinase defect, and ample *in vitro* evidence exists to support this contention.¹⁶⁸ In summary, evidence exists to indicate that glucotoxicity causes the acquired secondary component of insulin resistance in T2DM at least in part by reversibly decreasing the autophosphorylation/kinase activity of target tissue insulin receptors. With this analysis, the cellular mechanism underlying the primary inherited component of insulin resistance in T2DM remains to be elucidated. With regard to simple obesity, since these subjects are insulin resistant with normal receptor kinase activity, it would appear that the cause of impaired insulin action in those subjects with a reduced V_{max} involves some other postreceptor defect.

Insulin Receptor Subpopulations

This decrease in kinase activity in T2DM could be due to (1) a decrease in the intrinsic kinase activity of each individual receptor within the total receptor preparation, or (2) the existence of two

FIGURE 22-17. Percentage of receptors immunoprecipitable with anti-phosphotyrosine antibody. Receptors were labeled with ^{125}I -NAPA-DP-insulin, autophosphorylated, and immunoprecipitated. Washed receptor-antibody complexes were boiled in Laemmli's buffer and analyzed by SDS-polyacrylamide gel electrophoresis (7.5% resolving gel). Areas of the gel containing the ^{125}I -NAPA-DP-insulin-labeled β subunit were excised and counted in a gamma counter. Equal areas of the dried gel free of any ^{125}I activity were counted and subtracted as background. The graph shows the amount of ^{125}I -labeled insulin receptors immunoprecipitated by anti-phosphotyrosine antibody as a percentage of the total amount of receptors immunoprecipitated by the anti-insulin receptor antibody.

populations of receptors that bind insulin, one subpopulation having normal kinase activity and the other subpopulation having no kinase activity, with a relative increase in the kinase-defective population in T2DM. To discriminate between these two possibilities, phosphorylated ^{125}I -NAPA-DP-labeled receptors were immunoprecipitated using a monoclonal antireceptor antibody and an antiphosphotyrosine antibody.¹⁶⁹ ^{125}I -NAPA-DP-insulin is a photoactive insulin derivative which binds to the receptor α subunit; when exposed to UV light, the ^{125}I -NAPA-DP-insulin becomes activated and photoaffinity labels the insulin receptor by forming covalent bonds with the α subunit. The monoclonal anti-insulin receptor antibody immunoprecipitates all of the ^{125}I -NAPA-DP-labeled insulin receptors. In order to determine the proportion of insulin receptors that contain phosphotyrosine in the type 2 diabetic subjects compared to those of control subjects, an anti-phosphotyrosine antibody was used to immunoprecipitate only those insulin receptors containing phosphorylated tyrosine residues. Control studies showed that the monoclonal antireceptor antibody quantitatively immunoprecipitates the total receptor pool, whereas the phosphotyrosine antibody quantitatively immunoprecipitates only the autophosphorylated receptors. Therefore, a comparison of the ^{125}I counts immunoprecipitated by the antiphosphotyrosine antibody indicates the percentage of the total insulin receptors that are autophosphorylated and contain phosphotyrosine.

Figure 22-17 illustrates, for both control and type 2 diabetic subjects, the percentage of the insulin receptors, after maximal *in*

vitro insulin-stimulated autophosphorylation, that contain phosphotyrosine. Forty-three percent of the insulin receptors derived from control subjects contained phosphotyrosine residues, while only 14% of the type 2 diabetic subjects' insulin receptors were phosphorylated.¹⁶⁹ A much smaller fraction of the total receptors from type 2 diabetic subjects were able to undergo insulin-stimulated autophosphorylation compared to the normals. Additional studies have shown that the insulin receptors not precipitated by the antiphosphotyrosine antibody were completely devoid of kinase activity, and thus the kinase activity found in the total receptor preparations was attributable to those receptors precipitated by the antiphosphotyrosine antibody. These studies demonstrate the existence of at least two distinct populations of receptors—one containing phosphotyrosine residues and one apparently incapable of insulin-stimulated tyrosine phosphorylation. The results show that 43% of the receptors from nondiabetic subjects were capable of autophosphorylation, indicating that 50–60% of the receptors do not undergo tyrosine phosphorylation and presumably do not contribute to the kinase activity of the normal cell's complement of insulin receptors. Interestingly, since about 90% of the adipocyte insulin receptors are at the cell surface in the basal state,¹⁷⁰ most of these kinase-negative receptors must be at the cell surface, where they apparently bind insulin in a physiologic manner. In the type 2 diabetic group, only 14% of the receptors were capable of tyrosine autophosphorylation, and this decrease in the proportion of receptors that were phosphorylated appears to largely explain the defect in receptor kinase activity which has been observed in T2DM.^{75,162–165,171}

Glucose Transport

In vivo, insulin resistance is usually defined as an impaired ability of insulin to stimulate overall glucose disposal, and any cellular mechanism of insulin resistance must account for decreased glucose disposal. In the insulin action sequence, abnormalities in insulin receptor binding and receptor kinase activity *per se* do not account for all of the decreased glucose uptake. Decreased numbers of insulin receptors do not explain decrements in maximal insulin responsiveness in T2DM, since receptor downregulation does not commonly proceed below the level of spare insulin receptors. In addition, insulin concentrations that elicit maximal insulin bioeffects (1–5 ng/mL) produce only a submaximal degree of insulin receptor phosphorylation (see Fig. 22-16). This indicates, in a sense, that there is also “spare” insulin receptor kinase activity. Therefore, postreceptor defects may account for a large portion of insulin resistance. One potential cellular locus for such a postreceptor defect is the glucose transport effector system. In humans there are at least five known glucose transporter species (GLUT-1 to GLUT-5), each the product of a separate gene, with a distinct pattern of tissue expression for each transporter isoform. The insulin-regulatable glucose transporter is termed GLUT-4, and is almost exclusively expressed in skeletal muscle, cardiac muscle, and adipose tissue. As discussed in detail in Chap. 5, insulin stimulates glucose transport primarily by causing translocation of GLUT-4 proteins from an intracellular vesicular compartment to the plasma membrane. Once inserted into the plasma membrane, cellular glucose uptake is initiated. Consequently, insulin stimulation of glucose transport in target tissues reflects GLUT-4 activity. In this regard, decreased insulin-stimulated glucose transport has been observed in isolated adipocytes^{161,172–175} and skeletal muscle strips^{176–178} from obese and/or type 2 diabetic subjects. Decreased

insulin-stimulated glucose transport has also been found in cultured skeletal muscle cells derived from the insulin-resistant nonobese relatives of type 2 diabetic patients.¹⁷⁹

Although adipose tissue accounts for only a small amount of *vivo* glucose metabolism, whereas over 85% of insulin-stimulated glucose disposal occurs in skeletal muscle, for technical reasons most studies of glucose transport have been performed in isolated adipocytes. Figure 22-18 displays glucose transport dose-response curves using isolated adipocytes from normal, IGT, and type 2 diabetic subjects. In the IGT subjects, there is a rightward shift in the glucose transport dose-response curve with no change in the maximal response. This decrease in insulin sensitivity (rightward shifted curve) is largely accounted for by the decreased number of insulin receptors in cells from subjects with IGT. In the type 2 diabetic groups, however, a marked decrease in glucose transport rate is observed at all insulin concentrations. Thus there is a major decrease in glucose transport activity even at maximally effective insulin concentrations, and this *in vitro* reduction in glucose transport correlates quite well with the decrease in maximal overall glucose disposal rates observed *in vivo*. Similar results are seen in nondiabetic obese subjects, with a marked decrease in adipocyte glucose transport activity compared to controls (Fig. 22-19).

In extrapolating from *in vitro* adipocyte transport data to *in vivo* glucose disposal, several assumptions are made. First, it is assumed that adipose tissue glucose transport is reflective of muscle glucose transport, since muscle is the major site of insulin-stimulated glucose uptake. Available data strongly support this contention. Thus an excellent correlation has been found between adipocyte glucose transport activity and *in vivo* glucose disposal in individual type 2 diabetic or obese subjects both before^{161,17} and after^{180–182} therapy. Additionally, a number of more direct studies have shown that changes in adipocyte transport are parallel to quantitatively similar changes in skeletal muscle glucose transport in a number of different pathophysiologic conditions in rodents.^{183,184} Most importantly, the few studies that have been conducted on muscle fiber strips from normal, obese, and type 2 diabetic subjects have found that glucose transport is decreased in

FIGURE 22-18. Dose-response curve for insulin's ability to stimulate glucose transport (3-O-methylglucose uptake) in isolated adipocytes prepared from normal subjects, subjects with IGT, and obese or nonobese subjects with type 2 diabetes. The functional form of these dose-response curves is quite comparable to the shape of the dose-response curves for *in vivo* insulin-stimulated overall glucose disposal (Fig. 22-7).

FIGURE 22-19. Dose-response curves for insulin's ability to stimulate 3-O-methylglucose transport in isolated adipocytes from normal subjects (●), group I (○), and group II (▲) obese subjects.

the insulin-resistant groups¹⁷⁶⁻¹⁷⁸ (Fig. 22-20), and that, as in the adipocyte studies, insulin-stimulated glucose transport in isolated muscle fiber strips correlates with whole-body insulin sensitivity in normal and type 2 diabetic subjects.¹⁷⁷

The second assumption inherent in relating glucose transport to *in vivo* glucose disposal is that the transport step is rate-determining for glucose metabolism *in vivo*. Available data indicate that this is the case. For example, if intracellular metabolism, rather than transport, were limiting the rate of glucose disposal, one would expect an accumulation of free intracellular glucose. However, a build-up of intracellular glucose is not observed in skeletal muscle, even at brisk rates of glucose uptake.¹⁸⁵⁻¹⁸⁷ Additionally, apparent K_m values reported for *in vivo* glucose disposal¹⁸⁸ are similar to measured values of muscle glucose transport *in vitro*,¹⁸⁹ consistent with the view that transport governs glucose disposal. Furthermore, the insulin-induced increases in *in vitro* glucose transport are quite comparable to insulin-mediated increases in *in vivo* glucose disposal.

FIGURE 22-20. 3-O-Methylglucose transport in muscle fiber strips from nonobese subjects, morbidly obese subjects with normal glucose tolerance, and morbidly obese subjects with type 2 diabetes. (*Significantly different [$p < 0.05$] from nonobese group + insulin.) (Reprinted with permission from Dohm et al.¹⁷⁶)

Bonadonna and coworkers¹⁹⁰ used the forearm glucose balance technique in humans, combined with a simultaneous infusion of 3-O-methylglucose, to assess concomitant rates of glucose transport and *in vivo* muscle glucose uptake. They found that insulin-stimulated forearm glucose transport was very well correlated with overall muscle glucose disposal.¹⁹⁰ Studies with transgenic mice also support this concept. Thus, when GLUT-4 is overexpressed in skeletal muscle, enhanced insulin sensitivity and increased glucose disposal occur,¹⁹¹ pointing to the importance of glucose transport in regulating overall glucose metabolism.

Cline and colleagues,¹⁸⁷ using nuclear magnetic resonance spectroscopy to measure skeletal muscle glucose-6-phosphate levels and intracellular free glucose levels during a hyperinsulinemic, hyperglycemic clamp, have produced compelling *in vivo* evidence that glucose transport is also the rate-controlling step in insulin-stimulated muscle glucose uptake in T2DM. They found that the reduction in muscle glucose uptake and glycogen synthesis in patients with T2DM was associated with lower steady-state muscle glucose-6-phosphate levels and very low intracellular free glucose levels, implying a defect at the level of glucose transport. Of course, it is possible that the additional postglucose transport intracellular defects in glucose metabolism which have been reported^{123,135,192-197} alter the intracellular pathways for glucose metabolism, and contribute to abnormal glucose homeostasis.

Because decreased glucose transport is such a prominent defect in T2DM, a number of mechanistic studies have been conducted. Several groups have examined skeletal muscle GLUT-4 content at both the protein and mRNA levels, with uniform agreement. Skeletal muscle GLUT-4 mRNA and protein levels are normal in type 2 diabetic subjects.¹⁹⁸⁻²⁰⁰ Since total skeletal muscle GLUT-4 protein is not decreased in T2DM, the explanation for the decreased glucose transport activity is related to either decreased insulin-mediated translocation of GLUT-4 to the plasma membrane, decreased GLUT-4 intrinsic activity, or both. Evidence that insulin-stimulated translocation of GLUT-4 is impaired in skeletal muscle of obese and type 2 diabetic patients comes from the study of Kelley and associates.²⁰¹ These investigators used quantitative confocal laser scanning microscopy to study insulin-stimulated recruitment of GLUT-4 to the sarcolemma in muscle biopsies from normal, obese, and type 2 diabetic subjects. In the basal state, sarcolemmal GLUT-4 labeling was similar in the three groups, but in response to a 3-hour hyperinsulinemic euglycemic clamp (plasma insulin ~500–600 pmol/L), the increase in sarcolemmal GLUT-4 labeling in type 2 diabetic subjects and in obese nondiabetic subjects was only 25% of that in the controls. This defect in GLUT-4 translocation in the type 2 diabetic and obese subjects was associated with a marked impairment of insulin-stimulated muscle glucose transport as determined by positron emission tomography. Others using biochemical muscle subfractionation techniques have also suggested a defect in GLUT-4 translocation in patients with T2DM.²⁰²

A decrease in GLUT-4 intrinsic activity in T2DM is also a possibility. Such a defect could be a result of an alteration in the primary structure of the GLUT-4 protein due to genetic variation in the GLUT-4 gene. An answer to this question was made possible by the studies of Buse and associates, who elucidated the intron-exon structure of the human GLUT-4 gene.²⁰³ A determination of the coding sequences of GLUT-4 was conducted in seven typical type 2 diabetic patients.¹⁶⁶ In six patients, no abnormalities in the amino acid sequence were seen. Two patients were heterozygous and one homozygous for a silent polymorphism at nucleotide

position 535, but this polymorphism is commonly seen in nondiabetic individuals.²⁰⁴ Interestingly, one of the six patients had a substitution at codon 383, leading to an isoleucine-for-valine substitution at this position. The biological significance of this substitution is unclear, but larger-scale molecular scanning studies have verified that this mutation exists in only a small percentage (1–2%) of type 2 diabetic subjects, and it also exists in low frequency in nondiabetic subjects.²⁰⁴ Since no other mutations in the GLUT-4 gene have been identified in T2DM, it would appear that abnormalities in the GLUT-4 gene are rare in T2DM and that the coding sequence of GLUT-4 is not a diabetes gene locus.

Translocation of GLUT-4 involves a complex system, and an expanding list of proteins involved in GLUT-4 vesicle trafficking, regulation of membrane fusion, and endocytotic events are being identified.⁷² Thus it is quite possible that decreased GLUT-4 translocation could be due to altered expression or a functional defect of one or more of the GLUT-4 vesicle-trafficking proteins. An impairment of insulin signaling downstream of the receptor is also a likely cause of the decreased insulin-stimulated GLUT-4 translocation, and these are areas of intensive investigation.

Postreceptor Signaling Defects

After insulin binding and receptor autophosphorylation, a number of endogenous protein substrates are phosphorylated on tyrosine residues by the insulin receptor kinase. Insulin receptor substrate-1 (IRS-1) is the most thoroughly studied of these substrates. The ability of insulin to stimulate IRS-1 phosphorylation is decreased in both adipocytes²⁰⁵ and skeletal muscle^{206,207} from type 2 diabetic subjects. Rondinone and associates found that the IRS-1 protein content of adipose tissue was reduced by 70% in type 2 diabetic patients.²⁰⁸ Clearly, this reduction in IRS-1 protein content could contribute to the decrease in IRS-1 phosphorylation observed in adipocytes.²⁰⁵ However, this cannot be a factor in muscle because skeletal muscle IRS-1 levels are no different in type 2 diabetic patients than in lean or obese normal subjects.^{206,207,209} Insulin-stimulated phosphorylation of IRS-2 is also impaired in skeletal muscle from type 2 diabetic subjects.²¹⁰ Thus IRS-2 does not compensate for the defect of IRS-1 phosphorylation in skeletal muscle from diabetic patients.

Studies in adipocytes from control, obese, and type 2 diabetic subjects showed that the insulin dose-response curves for stimulation of tyrosine phosphorylation of IRS-1 and of the insulin receptor β subunit were almost identical and that the ability of phosphorylated insulin receptors to phosphorylate IRS-1 was normal.²⁰⁵ Because of this normal coupling between autophosphorylated β subunits and IRS-1 in adipocytes from type 2 diabetic patients, it is likely that the reduction in IRS-1 phosphorylation in adipocytes from these patients is essentially secondary to the insulin receptor kinase defect. Although similar detailed studies have not been performed in skeletal muscle, the finding that the abnormalities of the insulin receptor kinase and of IRS-1 phosphorylation in muscle parallel those in adipocytes suggests that the impairment of IRS-1 phosphorylation in muscle is also largely a consequence of the insulin receptor kinase defect.²⁰⁷

The enzyme PI-3-kinase is essential for insulin's effects on GLUT-4 translocation and glycogen synthase activation. As outlined earlier, this enzyme is activated by the binding of its regulatory subunit to tyrosine phosphorylated IRS-1 and IRS-2. Thus, tyrosine phosphorylation of IRS-1 and IRS-2 in response to insulin allows the regulatory subunit of PI-3-kinase to bind, leading to

activation of the catalytic subunit of the enzyme. Several studies have shown that association of the p85 regulatory subunit with IRS-1 and IRS-2 in response to insulin is impaired in muscle of type 2 diabetic patients and there is a corresponding defect of PI-3-kinase activation.^{207,210} Some^{207,211} but not all²¹⁰ studies have found that activation of muscle PI-3-kinase by insulin is also impaired in obese nondiabetic subjects.

Glycogen Synthesis

Glycogen synthase, the rate-controlling enzyme of glycogen synthesis, is another potential locus for acquired or inherited insulin resistance in T2DM. Glycogen synthase activity has been measured in muscle biopsy samples, and the level of enzyme activity correlates with the magnitude of nonoxidative glucose disposal, as measured by indirect calorimetry during glucose clamp studies. Diminished activation of glycogen synthase, decreased insulin-stimulated muscle glycogen deposition, impaired insulin-mediated glucose disposal, and defective nonoxidative glucose disposal all exist in type 2 diabetic subjects.^{194–197,212,213}

Glycogen synthase activity is reduced in T2DM by 35–50% as compared to controls at submaximal insulin levels, but the defect can be normalized by increasing insulin levels fourfold.¹⁹⁴ The glucose-6-phosphate activation constant was also increased, demonstrating a decreased sensitivity of muscle glycogen synthase in type 2 diabetes to allosteric activation by glucose-6-phosphate.¹⁹⁴ Importantly, the reduction in glycogen synthase activity in T2DM patients persists even when glucose uptake rates are normalized, indicating that the effect of insulin on glycogen synthesis is separate from its effect on glucose transport and that the defect in glycogen synthase activity is not simply due to a decline in glucose flux into the cell.¹⁹⁴

The defect in glycogen synthase activity can be partially reversed by an 8-week course of sulfonylurea therapy,¹⁹⁶ raising the possibility that the irreversible component may be genetic in nature. This is also suggested by a study of 16 type 2 diabetic subjects, 18 first-degree relatives of type 2 diabetic patients, and 16 nondiabetic subjects. Activation of muscle glycogen synthase was impaired in the relatives with a high known genetic risk of developing T2DM, indicating that this may represent an early defect in the evolution of T2DM.²¹⁴

To complement the cellular and biochemical studies cited above, the gene for glycogen synthase has been examined in T2DM. Groop and colleagues²¹⁵ reported an association between a rare polymorphism located in intronic sequences of the glycogen synthase gene and the type 2 diabetic phenotype in Finnish subjects. However, this association was not found in subsequent studies of French or American Caucasian subjects.^{216,217} Molecular scanning of the entire glycogen synthase gene in Finnish subjects identified a missense mutation at position 464 in exon 11 in only 2 of 228 type 2 diabetic patients but none of 154 controls.²¹⁸ Clearly, glycogen synthase gene mutations are uncommon in T2DM. A Danish study failed to detect any abnormalities in the coding sequence of the glycogen synthase gene in eight subjects with T2DM.²¹⁹ These authors did, however, find a 39% reduction in the steady-state level of glycogen synthase mRNA per microgram of muscle DNA, which correlated with the reduced total glycogen synthase activity of vastus lateralis muscle of type 2 diabetic subjects as compared to matched controls. Recent studies of twin pairs discordant for T2DM suggest that this reduction in muscle glycogen synthase mRNA and protein levels found in

some diabetic patients may be an acquired defect, perhaps secondary to hyperglycemia.²²⁰

FUNCTIONAL ASPECTS OF INSULIN RESISTANCE

From the earlier discussion, it is apparent that insulin resistance may be due to changes in insulin sensitivity, responsiveness, or both. This analysis relies on *in vivo* measures of the biologic effectiveness of a given concentration of insulin under steady-state conditions. However, steady-state analysis does not take into account potential alterations in the rate of insulin action. The kinetics of insulin action may be thought of as having two components: activation, and its opposite process, deactivation. The rate of activation of insulin's effects can be measured *in vivo* by assessing the time course of the increase in glucose disposal after starting an insulin infusion. Conversely, when insulin is removed from the system, deactivation of glucose disposal ensues. Early studies on the kinetics of insulin action were performed by Zierler and Rabinowitz.²²¹ These investigators infused insulin into the brachial artery and measured forearm glucose uptake. They found that when the insulin infusion was stopped, glucose uptake by the forearm persisted for up to an hour. They dubbed this the "memory effect" of insulin. Later, Sherwin and coworkers²²² and Insel and associates¹²⁴ confirmed that insulin's *in vivo* biologic effects dissipated slowly compared to the rapid decay of insulin from plasma. Finally, studies performed with isolated rat adipocytes have shown that deactivation of insulin's effect on glucose transport *in vitro* is slower than dissociation of insulin from its receptor. The glucose clamp technique is excellent for studying insulin's *in vivo* effects, and has generated much valuable information. However, it takes several hours before steady-state biologic effects of constant in-

sulin infusions are reached, and this clearly does not reproduce the phasic way in which insulin is delivered into the circulation under physiologic conditions of meal ingestion. Furthermore, assessments confined to steady-state measurements of insulin action will not detect kinetic alterations in the onset (activation) or offset (deactivation) of insulin's biologic effects. Indeed, in view of the fact that in response to food, insulin is secreted in a phasic rather than a constant manner, a defect in the dynamics of insulin action might be a physiologically more important manifestation of insulin resistance than reduced steady-state hormonal effects. To evaluate the above ideas, a modification of the euglycemic glucose clamp technique was used to test the hypothesis that a common human insulin-resistant state (obesity) is characterized by abnormally slow activation and rapid deactivation of insulin's effects to stimulate peripheral glucose uptake.²²³

In these studies, insulin was given as a constant infusion and the time course of activation of insulin-stimulated glucose disposal was measured. To study deactivation, the insulin infusion was stopped and the rate of fall in glucose disposal rate was observed. Insulin was infused intravenously at rates of 15, 40, 120, and 1200 mU/m²/min in a group of obese, nondiabetic patients compared to a group of lean normal control subjects. Comparable plasma insulin levels were attained in the two groups at each insulin infusion rate (Fig. 22-21). The time course of glucose disposal during and after the termination of the insulin infusions is shown in Fig. 22-22A. It can be seen from this figure that at each insulin infusion the normals achieved higher maximal insulin-stimulated glucose disposal rates. Additionally, the rate of activation of insulin-stimulated glucose disposal was slower in the obese subjects (Fig. 22-22B); in each case, the normal subjects had a steeper initial rise in insulin-stimulated glucose disposal. In addition, the rate of deactivation of insulin-stimulated glucose disposal occurred more quickly in the obese subjects. The apparent $t_{1/2}$

FIGURE 22-21. A. Serum insulin concentrations during and after discontinuation of insulin infusion rates of 15 (Δ), 40 ($\circ$), 120 (∇), and 1200 ($\square$) mU/m²/min in normal subjects. **B.** Serum insulin concentrations during and after discontinuation of insulin infusion rates of 15 ($\blacktriangle$), 40 ($\bullet$), 120 ($\blacktriangledown$), and 1200 ($\blacksquare$) mU/m²/min in obese subjects.

FIGURE 22-22A. A. Time course of glucose R_D during and after termination of insulin infusion rates of 15 ($\blacktriangle$), 40 ($\bullet$), 120 ($\blacktriangledown$), and 1200 ($\blacksquare$) $\text{mU/m}^2/\text{min}$ in obese subjects.

values for activation and deactivation are provided in Table 22-3. Since the insulin levels achieved in these studies were identical in obese and normal controls, the differences in glucose disposal must reflect differences in insulin action in normal and insulin-resistant subjects.

Thus, in insulin-resistant subjects the rate of activation of insulin-stimulated glucose disposal was two- to threefold slower compared to controls at every insulin level, and the rate of deactivation of insulin's effects was faster at all insulin levels. Therefore, one can postulate that the abnormal kinetics of insulin action in insulin-resistant obese subjects represent a functionally important manifestation of the insulin resistance in this condition. This concept is depicted in Fig. 22-23, which shows a theoretical time course of insulin action under conditions in which there is a 30% decrease in maximal steady-state insulin effects combined with a twofold slower rate of activation. At early points during the time course, the magnitude of the deficit in insulin's effects is far greater than that achieved at steady state. Considering that insulin rises and falls after meals, coupled with the kinetic defects in insulin action shown in Figs. 22-22 and 22-23, one can hypothesize that insulin's effects never reach steady state in the physiologic situation in obesity, and that the decrease in the rate of onset of insulin action and rapid deactivation serves to greatly minimize the biologic effects of the insulin secreted after oral glucose or meals in obesity, despite the fact that obese subjects are hyperinsulinemic.

To test this hypothesis, glucose disposal was measured in normal versus insulin-resistant obese subjects during phasic, rather than steady-state, insulin infusions. First, oral glucose tolerance

FIGURE 22-22B. Time course of activation (A, C) and deactivation (B, D) of insulin-stimulated glucose disposal. Data are expressed as a percentage of the maximal response, observed at the end of the infusion, and the insulin-stimulated glucose disposal rate (IGDR) is defined as the difference between the initial basal R_D value and the R_D values during and after cessation of the insulin infusion. Controls at insulin infusion rates of 15 (Δ), 40 ($\circ$), 120 (∇), and 1200 ($\square$) $\text{mU/m}^2/\text{min}$. Obese subjects at insulin infusion rates of 15 ($\blacktriangle$), 40 ($\bullet$), 120 ($\blacktriangledown$), and 1200 ($\blacksquare$) $\text{mU/m}^2/\text{min}$.

tests (OGTTs) with measurement of the plasma insulin profile were performed in a series of normal and obese subjects. The subjects then underwent two separate glucose clamp-type studies in each of which insulin was infused in a phasic stepped manner that reproduced the OGTT insulin profiles observed initially (Fig. 22-24). Each subject received an insulin infusion which reproduced the "normal" insulin profile as well as the "obese" insulin profile. Figure 22-25 demonstrates that this stepped insulin infusion method faithfully reproduced the insulin secretory profiles observed during the OGTTs. During these "insulin rate clamp" studies, stimulation of R_D and suppression of hepatic glucose production were measured. The results demonstrated that at comparable phasic, stepped insulin infusion rates, insulin-stimulated glucose disposal was reduced by 80–90% in the obese compared to

FIGURE 22-23. Effect of a theoretical defect in activation of the time course of glucose disposal. The lower curve depicts the results of a twofold slower rate of activation combined with a 30% decrease in maximal steady-state glucose disposal. As can be seen, this leads to a far greater decrease in the magnitude of the insulin effect at early time points than would be predicted based on the steady-state defect alone. Given the fact that insulin levels rise and fall relatively quickly (2–3 hours) after a meal, this kinetic defect is functionally important during the time interval over which postprandial insulin is normally secreted.

FIGURE 22-24. Glucose and insulin levels during oral glucose tolerance tests (OGTTs) in normal (○) and obese (●) subjects (* $p < 0.01$).

FIGURE 22-25. A. Insulin levels during the low-dose stepped insulin infusion in normal (○) and obese (●) subjects. Dotted line, mean OGTT insulin levels observed during OGTTs in normal subjects. B. Insulin levels during the high-dose stepped insulin infusion in normal (○) and obese (●) subjects. Dotted line, mean OGTT insulin levels observed during OGTTs in obese subjects.

control subjects (Fig. 22-26). More importantly, however, when the obese subjects were compared during the “hyperinsulinemic” infusion to the normal subjects at the “normoinsulinemic” infusion, a 60% reduction in glucose disposal was still observed in the obese group (Fig. 22-26C). Therefore, one can conclude that the postprandial hyperinsulinemia of obesity is unable to fully compensate for the insulin resistance, primarily due to the kinetic defects of insulin action, and that *in vivo* in the physiologic setting, insulin-stimulated glucose disposal is still markedly reduced in obesity.²²⁴ This conclusion was confirmed by carrying out glucose clamp studies in which insulin was infused at a constant rate to reach steady state at the same peak insulin levels as achieved during the phasic infusions. During these latter studies, the obese subjects achieved glucose disposal rates at hyperinsulinemia which were identical to the glucose disposal rates achieved in normal subjects at euglycemia²²⁴ (Fig. 22-27). Thus, the differences between phasic insulin infusions versus constant insulin infusions bring out the marked kinetic abnormalities of insulin action in obesity. Doeden and Rizza have obtained similar results using a modification of the glucose clamp technique.²²⁵

Because hyperinsulinemia does not fully compensate for insulin resistance in obesity, what does? Upon analysis of the oral glucose tolerance profile, it is clear that obese subjects, while not diabetic or glucose intolerant, are somewhat hyperglycemic compared to controls, and it is the hyperglycemia, by virtue of mass action, that helps compensate for the insulin resistance to restore glucose disposal to normal during meals. Thus, following a meal, insulin-resistant obese subjects achieve relatively normal rates of

FIGURE 22-26. A. Insulin-stimulated glucose disposal rate (IGDR) in normal (○) and obese (●) subjects at the low-dose insulin infusion. **Inset.** Total absolute incremental glucose disposal (IGD) over 4 hours in normal (open bars) and obese (solid bars) subjects. glucose disposal (and therefore can accommodate an incoming glucose load), but only at the expense of hyperinsulinemia and relative hyperglycemia.

In confirmation of this notion, studies have shown²²⁶ that when glucose disposal is measured during infusions in which both the OGTT insulin plus glucose profiles are reproduced in obese subjects, glucose disposal rates can be normalized. Thus, the mass action effects of postprandial glycemia contribute importantly to the maintenance of normal absolute rates of postprandial glucose disposal in obesity. Insulin resistance leads to a defect in postprandial glucose disposal in obesity. Hyperinsulinemia is an attempt to compensate for this defect by enhancing IMGU. When this compensatory effect is insufficient, absolute rates of glucose disposal remain impaired and the postprandial glucose level rises, so that by the mass action effect of glucose, glucose disposal rates are further augmented to a normal level (but at the expense of hyperinsulinemia and relative hyperglycemia). The obese patients depicted in Fig. 22-24 have substantial insulin resistance, and it can be roughly estimated that the hyperinsulinemia and postprandial glycemia each compensate ~50% for the deficit in glucose disposal induced by the insulin resistance. It seems likely that in subjects with milder states of insulin resistance, and/or in those obese subjects with particularly exuberant insulin secretion patterns, the hyperinsulinemia will be more effective as a compensatory mechanism.

Functional studies of adipocyte glucose transport in obesity have indicated that the kinetic abnormalities observed *in vivo* are most likely related to cellular defects in insulin action.¹⁷³ Thus, when the time course of insulin's ability to activate glucose transport was measured, a slower activation rate was observed in cells from obese subjects (Fig. 22-28); it took 15 ± 2 minutes to achieve half-maximal activation of insulin-stimulated glucose transport in cells from obese subjects compared to 9.4 ± 1.2 minutes ($p < 0.05$) in controls (Fig. 22-28). This decrease in the *in vitro* rate c

FIGURE 22-28. Time course of insulin-stimulated glucose transport. Adipocytes from lean (●) or obese (▲) subjects were exposed to a maximally effective concentration of insulin (25 ng/mL) at time 0, and 3-O-methylglucose uptake was measured at the indicated time points. Data are expressed as a percentage of the maximal effect for each subject and represent the mean ($\pm$ SEM).

activation of glucose transport correlates quite well with the slower rates of activation of glucose disposal *in vivo*.

Comparable findings have been reported in T2DM.¹⁷⁴ Thus, marked kinetic defects in activation and deactivation of insulin's *in vivo* effects on glucose disposal are found. Nolan and colleagues²²⁷ showed that the kinetic defect in insulin's ability to stimulate leg glucose uptake in type 2 diabetic patients was not accompanied by any delay in the activation of leg muscle insulin receptors by insulin. This suggests that the kinetic defect is distal to the insulin receptor. As in obesity, delayed activation of glucose transport is demonstrable in isolated adipocytes from type 2 diabetic patients. In general, the magnitude of the kinetic defects is greater in T2DM than in simple obesity. The presence of insulin resistance in T2DM, coupled with the impaired insulin secretion, explains the marked postprandial hyperglycemia in this condition. With this formulation it is evident that hyperglycemia is the major factor driving glucose disposal in T2DM, allowing these subjects to eventually dispose of an incoming meal or glucose load. These concepts may have implications regarding the treatment of type 2 diabetic patients. For example, intensive insulin therapy relies on algorithms for insulin delivery that were largely developed in type 1 diabetic patients. Clearly, such algorithms do not account for the kinetic defects present in insulin-resistant type 2 diabetic subjects. As such, these kinetic defects provide part of the explanation of why such large daily doses of insulin are needed to achieve ideal control in type 2 diabetic patients.

MOLECULAR GENETICS OF INSULIN RESISTANCE AND T2DM

Heredity plays a key role in the etiology of T2DM. Thus, although acquired factors such as obesity may be necessary for the phenotypic manifestation of T2DM, acquired factors alone are insufficient in most patients without preexisting genetic determinants.

Because insulin resistance predates the development of T2DM in most populations, it seems likely that some of the diabetogenic genes involve some aspect of insulin action. Available evidence indicates that T2DM is a genetically heterogeneous, polygenic disease. In other words, more than one diabetes gene occurs within a population, and it is possible that an individual must carry more than one abnormal gene in order to develop T2DM. For example, one or more genes involved in insulin action could be affected, along with a separately inherited defect responsible for the loss of β -cell function that occurs late in the course of T2DM.

Two basic strategies have been employed to identify potential diabetes genes. First is the candidate gene approach, in which it is hypothesized that a certain gene that has already been cloned and sequenced may be involved in the pathogenesis of T2DM. This hypothesis is then tested by comparing the sequence of this candidate gene in normal and type 2 diabetic subjects, looking for abnormalities in the disease state. The second approach makes use of polymorphic genetic markers or single nucleotide polymorphisms (SNPs), which are distributed throughout the genome, to map the location of the disease phenotype to a particular locus. This is done by determining whether the DNA markers cosegregate with the type 2 diabetic phenotype in a pedigree or population.

The insulin receptor, glycogen synthase and GLUT-4 have been examined as potential candidate genes in insulin resistance and T2DM. As discussed earlier, the primary sequences of these proteins are normal in T2DM, eliminating them as diabetes gene loci, except in rare individuals. In some populations, polymorphisms of IRS-1 may be two to three times more common in type 2 diabetic patients than in normal subjects, and in some studies an association between polymorphisms affecting the region of IRS-1 thought to be important for PI-3-kinase binding and a reduction in insulin sensitivity has been found.⁶⁷ The most common IRS-1 variant involves a substitution of arginine for glycine at codon 972. Expression of this Arg⁹⁷² IRS-1 variant in a skeletal muscle cell line resulted in decreased activation of PI-3-kinase, decreased insulin-stimulated GLUT-4 translocation, and activation of glycogen synthase compared to cells expressing wild-type IRS-1.²²⁸ Clearly, further studies are needed to assess the importance of these IRS-1 variants because they could contribute to the genetic basis of T2DM in a small subset of subjects. Very little information is available on other downstream insulin-signaling molecules. Several polymorphisms have been described in IRS-2, but there is general agreement that these are not associated with either insulin resistance or T2DM.^{229,230} A polymorphism of the p85 α subunit of PI-3-kinase in which isoleucine is substituted for methionine at codon 326 is common. In one study 2% of Danish Caucasians were found to be homozygous for the Met³²⁶Ile mutation, and this was associated with a reduction in insulin sensitivity, glucose effectiveness, and intravenous glucose tolerance.²³¹ However, subsequent studies do not support a role for this p85 α variant in the etiology of insulin resistance or T2DM.^{232,233}

The thiazolidinedione class of oral hypoglycemic agents act by increasing peripheral tissue insulin sensitivity. Because these agents work by binding to the nuclear peroxisome proliferator-activated receptor γ (PPAR- γ),²³⁴ it follows that this receptor may play a role in modulating insulin sensitivity. Because PPAR- γ is also an important regulator of adipogenesis, it could influence whole-body insulin sensitivity indirectly through an effect on fat mass and lipid metabolism.²³⁴ Several studies have therefore examined PPAR- γ as a potential candidate gene for insulin resistance and obesity in T2DM. The PPAR- γ gene gives rise to two alternate

transcripts, PPAR- γ 1 and PPAR- γ 2, with PPAR- γ 2 being expressed only in fat tissue. Molecular scanning of the PPAR- γ gene in diabetic Caucasians identified a Pro12Ala missense mutation in PPAR- γ 2.²³⁵ This mutation was associated with decreased PPAR- γ 2 receptor activity and is found in about 10% of Caucasians and Mexican-Americans. The Pro12Ala variant was associated with lower BMI and improved insulin sensitivity in Finnish subjects,²³⁶ but with a higher BMI and waist:hip ratio in Mexican-Americans.²³⁷ These contrasting findings may be due to the different populations studied. However, two other large studies of European Caucasians concluded that the Pro12Ala mutation is not associated with either obesity or T2DM.^{238,239} Another very rare inactivating mutation of PPAR- γ was found in three severely insulin resistant subjects characterized by marked hyperinsulinemia, acanthosis nigricans, and early-onset diabetes in the absence of obesity.²⁴⁰ Thus, inactivating PPAR- γ mutations may account for a small number of subjects with very unusual forms of insulin resistance, but PPAR- γ does not appear to be an insulin-resistance gene locus in patients predisposed to typical T2DM.

Given the importance of obesity in most type 2 diabetic patients, genes that predispose to obesity, and in particular a more central distribution of body fat, could also underlie the genetic predisposition. The discovery that the genetic syndromes of obesity and diabetes in the ob/ob mouse and db/db mouse were due, respectively, to failure of leptin production and an abnormality of the leptin receptor suggested that similar defects may play a role in human obesity. However, leptin levels are generally increased in human obesity, and leptin-receptor gene mutations do not appear to cosegregate with common obesity in humans.^{241,242} A polymorphism in the β_2 -adrenergic receptor was found to be associated with obesity; replacement of glutamine by glutamate at codon 27 (Gln27Glu) was found in 24% of obese women but only 3% of nonobese women.²⁴³ Homozygotes for Glu27 had on average 20 kg more adipose tissue, larger fat cells, higher fasting insulin levels, and a more central distribution of body fat. Although this particular polymorphism does not alter β -adrenoreceptor function, it is in strong linkage disequilibrium with another polymorphism (Arg16Gly) that is associated with increased sensitivity to agonist-induced downregulation.²⁴³

Gene mapping studies have generally sought linkage with the established type 2 diabetic phenotype rather than the underlying pathophysiological traits of insulin resistance and insulin secretory abnormalities (see Chap. 21). The few studies that have specifically looked for linkage between chromosomal loci and *in vivo* insulin action or fasting insulin levels (an index of insulin sensitivity) have been conducted in populations with a high prevalence of T2DM, such as the Pima Indians or Mexican-Americans. In Mexican-Americans, linkage was found between fasting insulin levels and markers on chromosome 3p.²⁴⁴ This region contains two possible candidate genes for insulin resistance, namely, a glycogen branching enzyme involved in glycogen synthesis and a peroxisomal branched-chain acyl-CoA oxidase that is involved in the degradation of long-branched fatty acids.²⁴⁴ Family studies in Pima Indians²⁴⁵ and Mexican-Americans²⁴⁶ have also suggested linkage between *in vivo* insulin resistance and a locus on chromosome 4q that encodes the intestinal fatty acid binding protein-2 (FABP-2). However, in three different European populations, no differences in allelic frequency at this locus were found between diabetic and nondiabetic individuals.²⁴⁷

A major development has been the positional cloning by Horikawa and colleagues of the gene for calpain 10 in the poly-

morphic "NIDDM1" region of chromosome 2 that shows linkage with T2DM in Mexican-Americans.²⁴⁸ Horikawa and colleague found that an SNP (UCSNP-43) in intron 3 of the calpain 10 gene showed an increased frequency of the common G allele in type diabetic patients compared to controls, and evidence for linkage with T2DM. Interestingly, subjects homozygous for the putative at risk G/G genotype were not at increased risk of T2DM, and it appears that other variations in the calpain 10 gene, in combination with the G allele at UCSNP-43, contribute to disease susceptibility. These investigators identified a number of high-risk calpain 10 gene haplotypes and found that the heterozygous 112/121 haplotype was the most common combination in Mexican-Americans with T2DM. They estimated that the 112/121 haplotype combination played a role in 14% of cases of T2DM in Mexican-Americans, but only 4% of Europeans participating in the study, in whom the combination was less common.²⁴⁸ Calpain 10 is a member of the family of cysteine proteases that have a ubiquitous tissue distribution. Its involvement in the mechanisms of insulin action or secretion is unknown and will be the focus of much research in light of these genetic findings. In one study, Pima Indians homozygous for the UCSNP-43 G allele had lower skeletal muscle calpain 10 mRNA levels, higher insulin levels 2 hours after an oral glucose load, and a marginally lower ($\sim 5\%$) glucose disposal rate during a glucose clamp.²⁴⁹

A major advance in our understanding of potential genetic mechanisms of insulin resistance leading to the development of the type 2 diabetic phenotype has come from transgenic mouse models in which a specific gene thought to play a key role in insulin action has been disrupted either at the whole-body level or in a specific tissue. Mice with targeted disruption of the insulin receptor die a few days after birth, while heterozygous animals have a virtually normal phenotype.²⁵⁰ These results in the heterozygous animals were perhaps not unexpected given the presence of spare insulin receptors on insulin target tissues. However, animals heterozygous for the IRS-1 null allele also do not develop diabetes, even though they display mild insulin resistance, hyperinsulinemia, and mildly impaired glucose tolerance as they age.^{251,252} Mice homozygous for the IRS-1 null allele show growth retardation, but again only mild insulin resistance, because IRS-2 appears to provide an alternative signaling pathway, particularly in liver.²⁵¹ IRS-1 and IRS-2 are not, however, simply interchangeable proteins. Thus IRS-2 is critical for certain actions of insulin. For example, in the liver it plays an important role in the activation of PI-3-kinase by insulin and regulation of gluconeogenic enzyme levels.^{253,254} Insulin signaling to PI-3-kinase in livers of IRS-2 $-/-$ mice is markedly impaired, and this is associated with impaired suppression of glucose production despite normal IRS-1 levels.^{253,255} Thus in hepatocytes IRS-1 does not compensate for IRS-2 deficiency, whereas IRS-2 is able to fully compensate for loss of IRS-1 in liver. Distinct roles of IRS-1 and IRS-2 have also been demonstrated in adipocytes. In brown adipocytes from IRS-2 knockout mice, insulin-stimulated glucose uptake is decreased by 50%. This defect is partially corrected by reexpression of IRS-2, but not by overexpression of IRS-1.²⁵⁶

Because severe deficiencies of insulin-signaling molecules are extremely rare in T2DM, and because T2DM is thought to be a polygenic disease, Bruning and colleagues²⁵² generated mice heterozygous for the null allele of more than one of the key signaling molecules. They found that mice heterozygous for the null alleles of both the insulin receptor and IRS-1 developed insulin resistance, hyperinsulinemia, and a progressive impairment of glucose

tolerance, with overt diabetes developing in approximately 40% of these mice by the age of 6 months.²⁵² Mice heterozygous for deficiencies of the insulin receptor, IRS-1, and IRS-2 had an even more profound degree of insulin resistance in muscle and liver, and a higher percentage went on to develop overt diabetes.

Taken together, these studies indicate that combinations of relatively minor defects, which in isolation may not cause significant phenotypic abnormalities, can act synergistically to cause insulin resistance and glucose intolerance. The particular mix of defects is likely to differ between different populations. Clearly, some defects may be acquired (e.g., the downregulation of insulin receptors by high circulating insulin levels), and act in concert with inherited genetic defects to produce significant insulin resistance and impairment of insulin secretion.

Another key finding from studies of mouse genetics is that insulin receptor signaling in islet β cells is essential for normal function. Thus, mice in which the insulin receptor gene has been specifically ablated in islet β cells, but not in other tissues, have smaller islet β cells, and no first-phase insulin secretion in response to glucose, reminiscent of the β -cell defect in T2DM.²⁵⁷ Second-phase glucose-induced insulin secretion is also blunted in these mice, and as they age, their glucose tolerance deteriorates, although they do not develop overt diabetes. IRS-2 rather than IRS-1 appears to be important for post-insulin-receptor signaling in islet β cells.²⁵³ IRS-2 also mediates IGF-1 receptor signaling in the β cells.²⁵⁸ IRS-2 thus plays a role in proliferative and neogenic responses. Thus IRS-2-deficient mice have a smaller β -cell mass than wild-type animals, whereas IRS-1-deficient mice develop β -cell hyperplasia to compensate for insulin resistance. IRS-2-deficient mice have hepatic, adipocyte, and muscle insulin resistance. Initially, they display fasting hyperinsulinemia and normal glucose-induced insulin secretion, but unlike IRS-1 deficient mice, their insulin secretion subsequently declines. They then become progressively hyperglycemic and overtly diabetic at several weeks of age.²⁵³ These studies indicate that functional insulin receptors and postreceptor signaling are essential for normal β -cell function, and raise the possibility that insulin resistance at the level of the β cell may contribute to the decline in insulin secretion that supervenes during the natural history of T2DM.

INSULIN-DEPENDENT (TYPE 1) DIABETES MELLITUS

When applied to the patient with type 1 diabetes mellitus (T1DM), the term "insulin resistance" is more difficult to evaluate. It usually denotes a patient who requires a large amount of insulin (>100 U/d) to maintain an acceptable level of diabetic control. These patients are unusual and sometimes have high titers of anti-insulin antibodies. However, the great majority of T1DM patients do not require more than 100 U/d for control. In fact, daily insulin dose requirements of C-peptide-negative type 1 diabetic patients are similar to endogenous 24-hour insulin secretion rates in normal subjects matched for age, sex, and BMI.²⁵⁹ Thus the question of whether the typical T1DM patient responds normally to insulin must be asked. No clear-cut answer emerges from the literature. One reason for this is that an insulin-dependent diabetic subject's insulin sensitivity is at least partially dependent on the degree of diabetic control, with resulting changes in the metabolic milieu, and these patients hardly represent a homogeneous population. By definition, subjects in poor control are more hyperglycemic, and the effect of hyperglycemia *per se* to induce a secondary state of

insulin resistance has already been discussed. In addition to hyperglycemia, changes in pH, counterregulatory hormones, and FFA concentrations can all influence insulin action, and as the degree of metabolic control deteriorates, these factors can change in such a way as to impair insulin action. Certainly, patients in ketoacidosis are insulin resistant.²⁶⁰ In a longitudinal study of 15 type 1 diabetic patients, Yki-Jarvinen and Koivisto²⁶¹ found a 32% decrease in *in vivo* insulin action 2 weeks from diagnosis. However, 3 months after starting insulin therapy, sensitivity was restored to normal. Other studies also suggest that insulin sensitivity may be normal if a T1DM patient is maintained in euglycemic control.^{108,262,263} Most T1DM patients have relatively poor glycemic control and lie somewhere between these extremes, so the status of insulin sensitivity is difficult to evaluate.

Studies using the forearm perfusion technique to assess insulin sensitivity have found that T1DM patients take up less glucose than normal, suggesting that peripheral tissues do not respond normally to insulin.²⁶⁴ Hepatic sensitivity to insulin, however, appears to be normal in most conventionally treated type 1 diabetic patients. Thus, although glucagon levels are often increased in T1DM patients, the ability of insulin to inhibit glucose production is normal or even increased;²⁶⁵ this might be explained by reduced hepatic sensitivity to glucagon.^{266,267} Studies in which whole-body insulin-stimulated glucose disposal in type 1 diabetes has been assessed using the glucose clamp technique at several insulin infusion rates have generally shown a decrease in the maximal response without any rightward shift in the insulin dose-response curve.^{262,263,268} This is thought to indicate that the abnormality is primarily distal to the insulin binding step. *In vitro* studies in isolated adipocytes from untreated type 1 diabetic patients showing a marked decrease in glucose transport at maximally stimulating insulin concentrations with no displacement of the insulin dose-response curve for this action of insulin, as well as unchanged insulin binding, support this view.²⁶⁹

When interpreting studies of insulin action in T1DM, it is important to bear in mind that in addition to the problem of variable diabetic control, the study populations may be heterogeneous. For example, a Danish study found that about 10% of patients originally classified as having type 1 diabetes, but without a high-risk HLA haplotype for the disease, carried mutations in the HNF-1 α gene and were thus MODY-3 patients.²⁷⁰ Furthermore, some studies may well have included some type 2 diabetic patients with very poor residual β -cell function. While the exact mechanism of insulin resistance in type 1 diabetic patients is unknown, since good metabolic control can reverse the insulin resistance, the defect must be acquired.^{261-263,268,269} Most likely, hyperglycemia is the major factor causing this secondary state of insulin resistance, although other acquired factors may be contributory. In a sense, this aspect of glucotoxicity represents another complication of chronic hyperglycemia, and provides additional rationale for attempts to achieve the best possible glycemic control in patients with diabetes.

UNUSUAL FORMS OF INSULIN RESISTANCE

Syndromes of Insulin Resistance and Acanthosis Nigricans

In a series of well-documented reports Flier, Kahn, Roth, and their colleagues have described a group of patients with extreme insulin resistance and marked acanthosis nigricans, in the absence of any other diseases associated with insulin resistance such as lipodystro-

phy, Cushing's disease, or acromegaly.²⁷¹⁻²⁷³ Patients with these syndromes are classified into two general groups.^{271,274} Type A patients tend to be young females with hirsutism, polycystic ovaries, mild virilism, coarse features, early accelerated growth, and, of course, acanthosis nigricans. Type B patients tend to be middle-aged females, although two males with this entity have now been reported. The syndrome in these patients is suggestive of an autoimmune disease with features such as hypergammaglobulinemia, proteinuria, hypocomplementemic nephritis, leukopenia, arthralgia, alopecia, enlarged salivary glands, and positive nuclear and anti-DNA antibodies. Patients with either of these subtypes have carbohydrate intolerance ranging from mild abnormalities of the oral glucose tolerance test to severe fasting hyperglycemia requiring enormous amounts of exogenous insulin. All of these patients are extremely hyperinsulinemic and respond poorly to the administration of exogenous insulin.

The mechanisms of this insulin resistance have been well studied, and in addition to learning about the cause of insulin resistance in a rare form of diabetes, these studies have provided important insights into overall insulin action. In type B patients, the mechanisms for the insulin resistance are fairly clear-cut. These patients have a severe defect in insulin binding to circulating monocytes, which is due primarily to an apparent reduction in binding affinity.^{271,272} These patients have circulating antibodies directed against some portion of the insulin receptor, which impairs insulin binding to the patients' cells.^{272,274} When immunoglobulins from these patients' sera are isolated and incubated *in vitro* with various cell types, subsequent measurements of insulin binding are also decreased. Furthermore, when the patients' freshly isolated circulating monocytes are "stripped" of adherent immunoglobulins, insulin binding returns to normal. Thus the role of the antireceptor antibody to directly interfere with the ability of insulin to bind to receptors *in vivo* is undisputed in these patients.

The insulin resistance of these patients can be quite severe, and one subject received as much as 177,000 U of insulin per day. The metabolic abnormalities in this syndrome can wax and wane, and a few patients have been described who have experienced complete remission of the insulin-resistant diabetic state with disappearance of antireceptor antibodies from the plasma. In a few patients remission occurred during immunosuppressive therapy;²⁷⁵ however, the documented occurrence of spontaneous remissions makes the potential causal relationship between drug therapy and remission unclear.

In other patients with genetic forms of severe insulin resistance (such as type A patients), various defects in insulin action have been described.^{274,276,277} Some of these patients show marked decreases in insulin binding affinity, whereas others show reduced levels of receptor expression. Intrinsic defects in receptor kinase activity or postreceptor abnormalities have also been reported. Many of these patients have been studied using molecular biologic approaches, and this has led to the identification of a large number of different mutations in the insulin receptor gene. These mutations can lead to abnormal insulin binding, decreased receptor kinase activity, impaired processing of the receptor polypeptide, or abnormal receptor gene transcription, and the reader is referred to Chap. 5 for a full discussion of this subject.

Generalized Lipodystrophy and Lipoatrophy

Many patients have been described as having generalized loss of subcutaneous and deep adipose tissue, hepatosplenomegaly, hyperlipoproteinemia, and diabetes mellitus. Frequently, these patients

also have acanthosis nigricans. Diabetes associated with this syndrome is of the insulin-resistant type. Thus these patients have highly elevated circulating plasma insulin levels and respond poorly to the administration of exogenous insulin. Similar findings can be observed in patients with partial lipodystrophy, in whom adipose tissue loss can occur exclusively above the waist, or less frequently, only below the waist. Both genetic and acquired forms of these lipodystrophic syndromes are recognized. A number of missense mutations in the gene for lamin A/C, a component of the nuclear envelope, have recently been identified in kindreds with the familial form of partial lipodystrophy.^{278,279} Presumably these mutations interfere with adipocyte differentiation. The gene for congenital generalized lipodystrophy has been mapped to a region of chromosome 9 that encodes the retinoid X receptor alpha gene.²⁸⁰ The latter would be a plausible candidate gene given its critical role in adipocyte differentiation.

The mechanism of the insulin resistance in the lipodystrophies is poorly understood and only a few conflicting reports exist. Oseid and colleagues²⁸¹ found that patients with generalized lipodystrophy have decreased insulin binding to circulating monocytes due to a slight decrease in receptor number and a large decrease in receptor affinity. However, upon fasting, the ability of cells from these patients to bind insulin increased normally, suggesting that this defect was secondary to the existing hyperinsulinemia rather than a primary abnormality. On the other hand, Kriauciunas and coworkers²⁸² found decreased insulin binding and decreased tyrosine kinase activity of receptors in cultured fibroblasts from patients with this syndrome, suggesting that the defect may be genetic and primary. However, others found normal insulin binding to cultured fibroblasts and to circulating monocytes from these patients.^{283,284} Possibly, these disparate findings indicate that different defects exist in different patients. The insulin resistance may well be secondary to the lipoatrophy and not due to any primary genetic defect in the insulin action pathway. A characteristic finding in patients with lipodystrophy is muscle hypertrophy associated with accumulation of triglyceride and glycogen within muscle fibers.²⁷⁶ The link between intramuscular fat and insulin resistance was discussed earlier. In two patients studied using the hyperinsulinemic euglycemic clamp, an impairment of HGO suppression by insulin was found together with a decrease in insulin-stimulated glucose disposal and a marked impairment of suppression of lipid oxidation.²⁸⁵ These findings could all be explained by the high circulating FFA and triglyceride levels and accumulation of fat in the liver and skeletal muscles of these patients.

Ataxia Telangiectasia

Ataxia telangiectasia is a rare recessive syndrome caused by inactivating mutations in a gene on chromosome 11 that encodes a protein that plays an important role in the cellular response to DNA damage.²⁸⁶ Homozygous patients develop progressive cerebellar ataxia, oculocutaneous telangiectasia, recurrent sinopulmonary infections, and a number of diverse abnormalities of the immune system. Frequently, this syndrome is accompanied by glucose intolerance and insulin resistance. Schalch and associates²⁸⁷ reported that about 60% of patients with this syndrome displayed glucose intolerance, hyperinsulinemia, and an attenuated hypoglycemic response to exogenously injected insulin. In the patients who have been well studied, secondary causes of insulin resistance such as circulating insulin antibodies, obesity, lipoatrophy, and excessive growth hormone or corticosteroid secretion have been ruled out. Thus the insulin resistance that may

occur in ataxia telangiectasia appears to be an intrinsic component of this syndrome.

In general, the degree of glucose intolerance has been mild, rarely requiring insulin therapy. Furthermore, a tendency toward exacerbation and remission of the insulin-resistant state has been noted. Earlier researchers²⁸⁷ recognized the resistance to the hypoglycemic effects of exogenous insulin and suggested an unknown circulating insulin antagonist might be a causative factor. Bar and associates⁸³ published detailed studies in two patients with ataxia telangiectasia and insulin resistance. A marked decrease in the binding affinity of insulin receptors on freshly isolated circulating monocytes was noted, while the insulin receptors of fibroblasts cultured from skin biopsies were normal. The fact that the insulin receptor abnormality did not persist in cell culture indicated that this defect was not genetic and was likely to be secondary to some aspect of the *in vivo* environment. In confirmation of this idea, these workers were able to demonstrate a circulating inhibitor of insulin binding, most likely an immunoglobulin, in the plasma of these patients. On the basis of these studies, it would appear that the insulin resistance in ataxia telangiectasia is due to the production of an antibody that inhibits insulin binding. Serial studies in one patient demonstrated the disappearance of this circulating inhibitor, coincident with the remission of the insulin resistance,⁸³ and this greatly strengthens the argument for a cause-and-effect relationship between these variables.

Leprechaunism

Leprechaunism is a very rare autosomal recessive disease characterized by an unusual facial appearance, hirsutism, clitorimegaly, acanthosis nigricans, sparse subcutaneous fat stores, and a number of other somatic abnormalities. This syndrome is almost always fatal. Most patients die during the first 1–2 years of life, with hyperglycemia and the histologic findings of β -cell hyperplasia. Several children with this syndrome have now been studied.^{276,277,288} In those patients in whom *in vivo* data are available, hyperinsulinemia and severe insulin resistance are present.^{277,288} The immunoreactive material in the plasma of these patients has been shown to be genuine insulin of normal biologic activity.²⁸⁸ Circulating insulin antagonists have not been detected, and this points to a cellular defect in insulin action.^{277,288} This concept is supported by molecular studies that have revealed the presence of insulin-receptor gene mutations in these patients. Interestingly, the mutations thus far described have been different, indicating that more than one genotype can lead to a common phenotype. It is important to eventually unravel the relationship between the receptor mutations and the multiple congenital anomalies displayed by these subjects, and this is discussed more thoroughly in Chap. 5.

Common Features of Severe Insulin-Resistant States

There are several somatic features that many of these unusual insulin-resistant states share (acanthosis nigricans, hirsutism, and mild virilism). Certainly, not every patient with one of these syndromes has these characteristics, but many do. Additionally, it is well known that severely obese insulin-resistant women often have acanthosis nigricans, hirsutism, and mild virilism. These frequent associations suggest some basic relationship between these phenomena, and it seems possible that some metabolic feature of hyperinsulinemia and insulin resistance leads to the associated so-

matic characteristics described. Although no mechanism is known, it is interesting to note that insulin is able to bind to IGF-1 receptors and can exert growth-like properties through this mechanism. Although insulin binds with a much higher affinity to the insulin receptor than to the IGF-1 receptor, it is possible to speculate that at very high circulating insulin levels (as seen in severe insulin-resistant states) insulin is capable of binding (or overlapping) into IGF-1 receptors, stimulating growth and proliferation of various cell types. With this formulation, high levels of circulating insulin could cross-react with other hormone receptors, possibly leading to some of the somatic features associated with a variety of insulin-resistant states.

Obesity and Diabetes Mellitus

P. Antonio Tataranni

Clifton Bogardus

OBESITY

Throughout evolution, animals and humans have developed redundant mechanisms promoting accumulation of fat tissue during periods of abundance to survive periods of famine. However, what once was an asset has become a liability in the current obesogenic environment of readily available high-fat foods and reduced physical activity.¹ As a consequence, obesity has reached epidemic proportions in both industrialized countries and in urbanized populations around the world.²

Obesity is clinically defined as a body mass index (BMI) of $\geq 30 \text{ kg/m}^2$ [a BMI of 30 represents an excess of weight of approximately 30 lb (14 kg) for any given height] (Table 23-1).³ In the United States during the late 1990s one out of two adults was overweight and one of four were obese.⁴ More alarming, the prevalence of obesity has been increasing drastically among children.⁵ The World Health Organization has identified obesity as one of the major emerging chronic diseases.² Obesity increases the risk for a number of noncommunicable diseases (i.e., type 2 diabetes, hypertension, dyslipidemias) and reduces life expectancy.⁶ In the U.S. the annual cost of obesity to the public health system is estimated to be nearly \$100 billion. This represents between 5% and 10% of the U.S. health care budget.⁷

The exact cause of obesity in the majority of humans is not known. It is, however, widely accepted that it results from a chronic imbalance between energy intake and energy expenditure (Fig. 23-1). Studies in twins,⁸ adoptees,⁹ and family members¹⁰ indicate that obesity is a heritable disease and that 70% of the interindividual variability in BMI is genetically determined.⁹ Because only 30% of BMI's heritable components can be attributable to familial traits such as daily energy expenditure (10–15%), respiratory quotient (5%), and spontaneous physical activity (10%),^{11–13} one has to conclude that a large proportion of the genetic variance in BMI may be due to the effect of genes on eating behavior and/or habitual daily physical activity (Fig. 23-2).

Recent research has provided an unprecedented expansion of our knowledge of the molecular mechanisms regulating food intake. Perhaps the greatest impact has resulted from cloning the genes corresponding to several mouse monogenic obesity syndromes and the subsequent characterization of the pathways involved.¹⁴ Many of these gene discoveries (*ob*, *db*, and *Ay*) have already led to potential anorexigenic drugs (leptin) or drug targets

(agonists for the leptin receptor and the melanocortin stimulating hormone receptor 4 [MC4-R], and antagonists for the neuropeptide Y receptors 1 and 5 [NPY1-R, NPY5-R] and others) currently in pharmaceutical development (see Chap. 10).

In contrast to animal models, the study of the molecular mechanisms and resulting behaviors that underlie excessive energy intake in humans has been very difficult. Nevertheless, the identification of severe hyperphagia in individuals with mutations of the leptin, leptin receptor, and MC4-receptor genes leaves little doubt that energy intake is as tightly regulated in humans as it is in animals, and suggests that these are highly conserved pathways¹⁵ (Table 23-2). Furthermore, based on the results that have emerged from the recent use of new imaging techniques (such as positron emission tomography and functional MRI), it seems likely that brain responses to a meal may be substantially different between lean and obese subjects.^{16,17} Such techniques applied to postobese subjects as well as subjects suffering from eating disorders may help identify the neurological pathways responsible for hyperphagia and obesity in humans.

Past difficulties in measuring habitual physical activity in humans have largely been alleviated by the advent of the doubly labeled water technique.¹⁸ Thus in the near future it should be possible to better understand the interaction between the energy expended in daily physical activities and the development of obesity in children and adults.

A greater knowledge of the pathophysiology of obesity will ultimately come from the current efforts to isolate all of the genes related to weight gain. Over the past 5 years, genetic linkage studies have increasingly focused on complex traits such as obesity. Genome-wide scans have been completed in Mexican-Americans,¹⁹ in Pima Indians,^{20,21} in a diverse population of whites and blacks,²² in French-Canadian families,²³ and in French families.²⁴ From these studies major loci linked to obesity have been found on chromosomes 2, 5, 10, 11, and 20. Those areas of the genome are currently under intense investigation as they may lead to the cloning of obesity susceptibility genes.

While obesity is likely a disease with multiple genetic and molecular causes, the impact of an obesogenic environment on this disease is substantial.²⁵ Therefore research should be conducted to uncover the major environmental determinants of obesity, and most importantly, to understand which are realistically modifiable.

TABLE 23-1. Classification of Overweight and Obesity by Body Mass Index (BMI) According to the 1998 National Institutes of Health Guidelines

	Obesity Class	BMI kg/m ²
Underweight		<18.5
Normal		18.5–24.9
Overweight		25.0–29.9
Obesity	I	30.0–34.9
	II	35.0–39.9
Extreme obesity	III	≥40

FIGURE 23-1. Obesity is the result of a chronic imbalance between energy intake and energy expenditure. Obesity susceptibility genes and their interaction with the obesogenic environment are likely to control both sides of the energy balance equation (i.e., energy intake and energy expenditure).

FIGURE 23-2. Studies in twins, adoptees, and family members indicate that approximately 70% of the interindividual variability in BMI is attributable to genetic factors. From prospective studies in Pima Indians, we can ascribe 10% of the variability in BMI to resting metabolic rate (RMR), 5% to fat oxidation (estimated from the respiratory quotient, RQ), and another 10% is likely due to the level of spontaneous physical activity (SPA)/fidgeting. Based on these data we estimate that at least 40% of the variability in BMI is related to genetic factors involved in the regulation of food intake (hyperphagia) and/or volitional activity (inactivity). Future studies are warranted to confirm these theoretical estimates.

TABLE 23-2. Some Forms of Human Obesity Caused by Single Gene Mutations

Gene	Mutation	Location
LEP	G deletion @ codon 133 C → T codon 105 exon 3	7q31
LEPR	G → A exon 16	1p31
MC4-R	CTCT deletion @ codon 211 GATT insertion @ nt732	18q21.3

LEP, leptin gene; LEPR, leptin receptor gene; MC4-R melanocortin = stimulating hormone receptor-4 gene.

ASSOCIATION BETWEEN OBESITY AND T2DM

Individuals with type 2 diabetes mellitus (T2DM) are so commonly obese that Ethan Sims coined the term *diabesity* to describe this increasingly common syndrome. The association between obesity and T2DM has been observed in comparisons of different populations and within populations. In 10 different populations from divergent areas of the world, West and Kalbfleish discovered a strong correlation between prevalence of mean percentage standard weight and prevalence of T2DM.²⁶ Similar associations were found within populations, starting as early as 1921 in a study by Joslin.²⁷ Epidemiologic data indicates that both obesity and T2DM are more prevalent in affluent than in poor countries, suggesting that differences in life style and nutrition account for some of the differences observed between populations. However, within the same environment, certain ethnic groups have a markedly increased prevalence of obesity and T2DM. This has been interpreted by some to indicate that a common genetic predisposition may underlie the increased propensity for obesity and T2DM.

In addition to being more obese than nondiabetic people, people with T2DM have a more central distribution of body fat. As early as 1956, Vague suggested that central obesity was more common in people with T2DM.²⁸ Using different measures of body fat distribution, Feldman and colleagues confirmed these findings.²⁹ In a survey of over 30,000 women, Hartz and associates reported a higher prevalence of T2DM in women with a greater proportion of body fat at the waist relative to the hips, even at comparable degrees of obesity.³⁰ In addition to these intrapopulation surveys, West reported that the Plains Indians of Oklahoma, a population with a high prevalence of T2DM, had a more central distribution of body fat when compared with whites in the U.S. population, a group with a lower prevalence of T2DM.³¹

Despite the overwhelming evidence showing the association between obesity and diabetes, a closer look at these cross-sectional data indicates that obesity is neither necessary nor sufficient for the development of T2DM. First, a number of lean people have diabetes.³² Second, in some populations a high prevalence of obesity is associated with a low prevalence of T2DM³³ and pairs of diabetic monozygotic twins who are discordant for body weight have been described.³⁴ Third, in most populations obesity is more prevalent in females than in males, whereas the prevalence of T2DM is no different between genders. Finally and most importantly, in all populations a vast majority of the individuals who are obese do not

FIGURE 23-3. Incidence of T2DM correlated with BMI and parental diabetes in Pima Indians. This and other evidence (see text) indicates that obesity in neither sufficient nor necessary for the development of T2DM. (Adapted from Knowler et al.³⁶)

have T2DM. Although more than 50% of U.S. individuals are overweight, less than 10% of the population has T2DM (see Chap. 19 for a complete review). Among Caucasians³⁵ and Pima Indians³⁶ the latter, a population with one of the highest reported prevalence rates of obesity and diabetes in the world, the association between obesity and diabetes is strongly influenced by parental diabetes (Fig. 23-3). This seems to suggest that obesity may be more harmful in subjects who are genetically predisposed to develop T2DM. Cross-sectional studies do not establish whether obesity and T2DM are causally related, or if there is a third factor that causes both. However, prospective and longitudinal studies strongly support a direct role of obesity in the pathogenesis of diabetes.

OBESITY IS A RISK FACTOR FOR T2DM

Prospective studies on Caucasians in Norway,³⁷ Sweden,³⁸ Israel,³⁹ and the United States,^{35,40,41} as well as Mexican-Americans in Texas⁴² and Pima Indians in Arizona⁴³ have shown conclusively that obesity is a major risk factor for T2DM. Furthermore, studies of Israelis³⁹ and Pima Indians⁴⁴ have indicated that duration of obesity, in addition to degree of obesity, is a risk factor for T2DM. The risk of T2DM in Pima Indians is twice as high in those who have been obese for 10 years or more compared with those obese for less than 5 years.⁴⁴ A central distribution of body fat is also a major risk factor for T2DM, independently of the degree of obesity. This was demonstrated in prospective studies of Swedish, Pima Indian, and

Japanese populations, irrespective of the methodology used to assess body fat distribution.^{43,45,46}

Obesity and visceral fat are neither the only nor the strongest predictors of T2DM. The relative role of obesity, body fat distribution, insulin sensitivity, insulin secretion, and hepatic glucose production was assessed in a prospective study of nondiabetic Pima Indians followed annually to detect the development of T2DM and to compare baseline measurements of those who developed the disease and those who did not.⁴³ Consistent with studies in other populations, univariate analyses revealed that insulin resistance is the single strongest predictor of T2DM (Table 23-3). In multivariate analyses, insulin resistance and insulin secretory dysfunction had an independent and cumulative effect on the development of diabetes, while hepatic glucose production did not (Fig. 23-4). The degree of obesity had little or no effect in predicting diabetes when insulin resistance was taken into account, suggesting that insulin resistance may be the major mechanism behind the association of obesity with increased risk of diabetes. In contrast, insulin resistance remained a strong predictor of T2DM when obesity (and insulin secretory function) was taken into account, indicating that in this population, insulin resistance predisposes to T2DM as a result of factors other than obesity alone. Central obesity, which predicts diabetes in other populations, was also predictive in Pima Indians and remained a significant risk factor when percentage of body fat and insulin resistance were taken into account. A reduced acute insulin response to glucose was also a significant independent risk factor.⁴³

TABLE 23-3. Risk Factors for the Development Type 2 Diabetes in 200 Pima Indians

Factor	Values at 10th or 90th percentile*	Relative Hazard	95 % CI
Body fat (%)	22, 52	7.8	2.3–26.8
Ratio of waist to thigh circumference	1.4, 1.8	12.2	4.0–36.8
M ₁₃₀ (mg glucose/kg MBS · min)	4.4, 2.0	31.1	4.9–197.1
Hepatic glucose production (mg/kg MBS · min)	1.79, 2.47	1.3	0.3–1.9
Acute insulin response (μ U/mL)	402, 104	2.2	0.9–5.9

M₁₃₀ represents glucose uptake at a mean plasma insulin concentration of 130 μ U/mL during euglycemia. MBS, metabolic body size (fat-free mass + 17 kg). Relative hazards were computed by proportional hazard analysis. *The first value in this column is the value associated with a lower risk of diabetes.

Together, prospective studies in Pimas and other populations indicate that obesity and defects in both insulin action and insulin secretion predispose to diabetes, but they give little information about the time course of these abnormalities and how they interact with one another. Longitudinal data in a group of Pima Indians followed for 5 years indicate that the transition from normal glucose tolerance to impaired glucose tolerance was associated with increased body weight, a decline in insulin action, and a decline in insulin secretion, but no changes in hepatic glucose production.⁴⁷ Further increase in body weight and further decrease in both insulin action and insulin secretion, but an increase in hepatic glucose production, characterized progression from IGT to diabetes. By comparison, in Pimas who remained NGT over the same period

of time, a twofold smaller increase in body weight was associated with a decline in insulin action and an increase in insulin secretion^{47,48} (Fig. 23-5). These data are consistent with a pathogenic role of obesity and longer duration in the progressive impairment of insulin action and insulin secretion that lead to diabetes.

OBESITY AND INSULIN RESISTANCE

Experimental weight gain causes hyperinsulinemia and insulin resistance in animals and humans.^{49–53} The effect of short-term overnutrition on insulin action is thought to be mediated by a decrease in muscle glycogen synthase activity and glycogenesis.⁵¹

FIGURE 23-4. Seven-year cumulative incidence of T2DM in Pima Indians. This analysis shows the independent and additive effect of insulin resistance and insulin secretory dysfunction on the development of T2DM in this population.

FIGURE 23-5. Relation of changes in 2-hour glucose concentration, insulin action ($\Delta M\text{-low}$), and insulin secretion (ΔAIR) to change in body weight in 209 Pima Indians with normal (NGT) or impaired (IGT) glucose tolerance at baseline, who were studied a second time while still free of diabetes after either losing or gaining weight over an average of 2.5 years. While weight gain was associated with a similar decline in insulin action in individuals with NGT and IGT (**middle panels**), the effect of weight gain on insulin secretory function was opposite in the two groups (**lower panels**). Thus, weight gain seems to have more detrimental effects in subjects with IGT than in subjects with NGT, since in the former insulin secretion fails to increase to compensate for the decreased insulin action. Consequently, the raise in 2-hour glucose in response to the same degree of weight gain is greater in people with IGT compared to people with NGT (**upper panels**). (Adapted from Weyer et al.⁴⁸)

Recent data suggest that this may be due to activation of the intracellular hexosamine pathway in response to excessive availability of nutrients.⁵⁴

The relationship between degree of obesity and *in vivo* insulin action has been investigated extensively. In nondiabetic Pima Indians the relationship between obesity and insulin action was

studied using a two-step euglycemic-hyperinsulinemic clamp technique.⁵⁵ In combination with indirect calorimetry, this technique allows the assessment of whole body (reflecting mostly skeletal muscle glucose metabolism) insulin-mediated glucose disposal and its two major components, oxidative and nonoxidative (glycogen storage) glucose disposal. A negative, nonlinear relationship

FIGURE 23-6. The relation between insulin-mediated glucose disposal (M) during a hyperinsulinemic euglycemic clamp and percentage of body fat study in 280 Pima Indians with either NGT ($n = 179$, open circles), IGT ($n = 79$, gray circles), or T2DM ($n = 29$, dark circles). At each level of adiposity, individuals with a relatively high, normal, or low M can be identified.

between the degree of obesity and *in vivo* insulin action at physiologic insulin concentrations was observed⁵⁵⁻⁵⁷ (Fig. 23-6). At maximally-stimulating plasma insulin concentrations there was a significant, negative linear relationship between degree of obesity and insulin action. It is important to point out that in Pima Indians, adiposity only accounts for approximately 36% of the variance in insulin action at physiologic insulin concentration, and even less, approximately 15%, at maximally-stimulating insulin concentrations.⁵⁵⁻⁵⁷ While some of this variance can be explained by differences in body fat distribution, this indicates that some very obese individuals can have a normal peripheral tissue sensitivity to the effect of insulin on glucose uptake (Fig. 23-6).

Many studies have indicated that over a wide range of insulin action, from the greatest *in vivo* insulin resistance to the greatest insulin sensitivity, glucose storage, not glucose oxidation, makes a progressively greater contribution to glucose uptake.⁵⁸⁻⁶² Together with the evidence that during a hyperinsulinemic euglycemic clamp there is little hepatic glucose uptake⁶³⁻⁶⁵ but significant peripheral glucose uptake, these studies emphasize the role of skeletal muscle glucose storage in determining insulin resistance. In 1989, Shulman and associates demonstrated directly that the rate of insulin-mediated glycogenesis, measured by nuclear magnetic resonance, was reduced in people with T2DM compared with nondiabetic subjects.⁶⁶ Despite the many theories proposed to explain

the etiologic link between obesity and insulin resistance, a convincing explanation of how excess adiposity and/or its metabolic and hormonal consequences impair glucose uptake and storage in the muscle remains elusive.

Role of Free Fatty Acids (FFA)

After years of controversy, there is now very strong evidence that acute elevation of plasma FFA levels, such as can be generated by intralipid/heparin infusion, can result in insulin resistance.⁶⁷ Furthermore, acute^{68,69} and chronic⁷⁰ lowering of FFA improves insulin sensitivity.

The question as to how an increased fatty acid supply from fat depots, especially visceral adipose tissue, induces insulin resistance in peripheral tissues has been difficult to resolve. Lipolytic activity in abdominal adipocytes is considerably higher than in subcutaneous adipocytes.⁷¹ Because FFA released from the abdominal fat deposits are delivered directly to the liver through the portal vein, hepatic insulin resistance, accompanied by increased gluconeogenesis and increased lipoprotein and triglyceride export to other tissues, has been invoked as a possible mechanism. However, it has been difficult to directly demonstrate an increase in FFA flux to the muscle in obese subjects and in subjects with increased visceral obesity, and in fact the reverse has been reported.⁷² Never-

theless, insulin sensitivity in animals and humans has been found to be inversely related to total muscle triglyceride content as measured in muscle biopsies.⁷³⁻⁷⁵ In humans, this correlation is much stronger when intramyocellular fat is the measured variable.⁷⁶ While there appears to be increasing evidence for an accumulation of muscle lipid in insulin resistance states in humans, the causal mechanism that links tissue accumulation of fat and reduced glucose uptake remains to be established.

It has been proposed that increased availability of FFA or ketones for oxidation may be responsible for an inhibition of carbohydrate metabolism in muscle, thus producing a reduction in glucose tolerance. The concept has been extended to suggest that one role of insulin is to control glucose uptake by controlling the rate of release of FFA from adipose tissue.^{77,78-80} However, in both humans and rodents the effect of intralipid/heparin infusion on insulin resistance takes several hours to occur.^{67,81} Thus the prompt effect of FFA to reduce glucose oxidation/glycolysis at the mitochondrial level by competing for the same oxidative pathways as first described by Randle and colleagues⁷⁷ is at best an incomplete explanation for a direct effect of FFA on insulin resistance.

While there is substantial evidence of a primary role of skeletal muscle glucose storage (not oxidation) in determining insulin resistance, an unequivocal biochemical explanation for a role for FFA in regulating glycogen synthesis is lacking. Some possible mechanisms have been proposed. Long-chain acyl CoA (LCACs, the activated form of FFA that can be transported across the mitochondrial membrane for oxidation) and especially palmitoyl CoA have been shown to inhibit the activity of liver glycogen synthase,⁸² but there are no reports of this effect in muscle. The effect of FFA on glucose storage may be indirectly mediated via an inhibitory effect on insulin signaling and/or glucose transport. Some evidence points to the possible modulatory effect of LCACs on PKC activity⁸³ and its inhibition of insulin-mediated glycogen synthesis. In animal and human studies, a significant correlation has been found between FFA composition of muscle membranes and insulin action.^{84,85} The mechanisms by which lipid composition of the membrane influences insulin action are not clear but may involve changing membrane fluidity, which could affect insulin and other membrane receptor action.⁸⁶ FFA may directly affect glucose transport, and there is substantial evidence that LCACs are intimately involved in the regulation of the normal translocation of GLUT-4-containing vesicles.⁸⁷⁻⁸⁹ UDP-N-acetylglucosamine (UDP-N-GlcNAc) is the end product of the hexosamine pathway and stimulation of this pathway by hyperglycemia, infusion of glucosamine, or increased availability of FFA causes insulin resistance in the muscle.⁹⁰ By glycosylation and stabilization of transcription factors, UDP-N-GlcNAc may regulate expression of genes involved in the control of glycogen synthesis.

Role of Adipocyte Secreted Hormones

While the response of adipocytes to sex steroids and glucocorticoids has been known for a long time,⁹¹ it is only recently that the adipose tissue has been recognized as an endocrine and paracrine organ from which a number of signals emanate. These include leptin, tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), complement C3 and its cleavage product acylation stimulating protein (ASP), enzymes of lipoprotein metabolism (LPL, CETP, and Apo-E), growth factors (TGF β and IGF-1), angiotensinogen, and PAI-1.⁹² It has been proposed that the role of adipose tissue in

regulating glucose metabolism may in part be explained through the action of leptin and the other adipocyte-secreted cytokine: TNF- α and IL-6 on peripheral tissues (Fig. 23-7).

Leptin levels are usually elevated in proportion to the degree of obesity in animals and humans.^{93,94} Leptin has been shown to have both central and peripheral effects.⁹⁵⁻⁹⁷ Experimental studies have suggested that leptin may impair insulin signaling both in the skeletal muscle and the adipose tissue. Leptin impairs insulin-mediated glucose uptake in mouse myotubes by inhibiting phosphorylation of IRS-1.⁹⁸ The same type of mechanism was reported for the insulin-mediated glucose uptake inhibition induced by leptin in Hep-G2 cells.⁹⁹ In rat adipocytes, leptin has been found to inhibit insulin-mediated glucose uptake, possibly via PKA activation.¹⁰⁰ These *in vitro* data contrast sharply with the data from experiments in several animal models of obesity and diabetes that show improvement in glucose/insulin metabolism in response to peripheral administration of leptin.¹⁰¹⁻¹⁰⁴ Leptin administration in humans is not associated with the development of diabetes in the short-term.¹⁰⁵ Thus the role of leptin as a mediator of the insulin resistance observed in obese individuals remains largely unsubstantiated and the balance of data suggest that leptin improves insulin sensitivity.

Adipose tissue is a significant source of endogenous TNF- α production and its expression is elevated in association with obesity in both animals and humans.^{106,107} Adipocytes are also responsible for the expression of the soluble form of both type 1 and type 2 TNF- α receptors.¹⁰⁸ Release from subcutaneous adipose tissue of both forms of TNF- α receptors into the circulation has been observed, but not release of TNF- α itself.^{108,109} The exact role of the soluble receptors in modulating the effects of TNF- α in target tissues is not well understood. *In vitro* studies suggest that TNF- α impairs insulin signaling, but the exact mechanism is still under investigation. TNF- α has been reported to decrease phosphorylation of IR/IRS-1,¹¹⁰ decrease IRS-1 and GLUT-4 expression,¹¹¹ and increase intracellular calcium concentration.¹¹² However, whether TNF- α is an endocrine or paracrine signal from distant or local adipocytes to the muscle remains the subject of some debate. Therefore, the *in vivo* significance of these data is as yet unclear.⁹²

Like TNF- α , IL-6 is a proinflammatory cytokine with potent actions in host defense. IL-6 is also expressed in and released by adipose tissue and its circulating concentration increases with obesity.^{113,114} In animals, IL-6 has been shown to stimulate insulin secretion.¹¹⁵ In humans, IL-6 was found to increase hepatic glucose release and to induce the release of glucagon and cortisol.¹¹⁵ Thus, a direct role of IL-6 in causing insulin-resistance in the obese state is currently only based on circumstantial evidence.

Human adipocytes also synthesize and secrete the three proteins of the alternative complement pathway: complement C3, factor B, and factor D (adipsin). The interaction of these three factors results in the generation of C3a, which is rapidly converted to C3adesarg, also termed acylation stimulating protein (ASP).¹¹⁶ *In vitro* studies indicate that ASP stimulates glucose uptake in adipocytes,¹¹⁷ fibroblasts,¹¹⁸ and myotubes.¹¹⁹ Experimental data indicate that ASP stimulates the translocation of glucose transporters to the cell surface and that this effect is independent of insulin.^{118,119} Elevated C3 levels have been reported in association with obesity and other conditions associated with insulin resistance.¹²⁰⁻¹²² A negative correlation between insulin action and C3, but not ASP, plasma concentration has been reported in Pima Indians.¹²³ The exact biological mechanism underlying this association remains obscure, especially in view of the positive effects of ASP on glucose metabolism.

FIGURE 23-7. The adipose tissue is an endocrine organ. Several signals (endocrine, paracrine, and metabolic) emanate from adipocytes and are believed to affect several organs including brain, liver, skeletal muscle, and pancreas. The strength and direction of the effect of the signals emanating from the adipose tissue to other organs are the object of intense investigation.

Role of Obesity-Induced Changes in Skeletal Muscle

Obesity is associated with an increase in both fat mass and fat-free mass.¹²⁴ A role for the increase in fat-free tissue in producing insulin resistance has been studied in the past. With an increase in fat-free mass, muscle cells are hypertrophied and capillaries in the muscle are more widely spaced. Several human studies have indicated that muscle cell size and muscle capillary supply are associated with changes in fasting insulin concentration and glucose tolerance.^{125–127} It has been proposed that the association between obesity-induced changes in skeletal muscle morphology and insulin action may be explained by the fact that lower capillary density results in reduced access of insulin to muscle of obese subjects.¹²⁸ Studies of insulin kinetics have indicated that insulin penetrates the capillary wall slowly and equilibrates slowly in a non-vascular compartment.¹²⁹ If muscle cell membranes are able to take

up and degrade insulin more rapidly than the diffusion of insulin from capillary to interstitial space and down to fibers, then physiologic effects would be important. Theoretical models based on the principles that insulin diffuses from the capillary and is taken up and degraded by muscle cell membrane, predict that the average insulin concentration around a hypertrophied muscle cell with a poor capillary supply will be reduced even at steady state.⁵⁷ In support of this theory, a reduced capillary density,¹²⁸ a delayed onset of insulin action in the muscle,^{130,131} and a 26% lower tissue insulin concentration at the same plasma concentration have been observed in obese compared with lean individuals.¹³²

OBESITY AND INSULIN SECRETION

FFA serve as an important energy source for most body tissues, but they have a broader function in whole-body fuel homeostasis by

virtue of their ability to act as signals in a variety of cellular processes. One such role of FFA is to enhance the responsiveness of the pancreas to a variety of insulin secretagogues. However, recent studies indicate that chronic exposure of the pancreas to excessive FFA concentration may have deleterious effects on the β cells.¹³³

Studies in animals indicate that FFA are indispensable to the β cells for stimulus-secretion coupling during fasting. In fasted rats, β cells are virtually unresponsive if FFA are lowered by an infusion of nicotinic acid before a glucose load, and the insulinotropic efficiency of FFA increases with their degree of saturation.^{134,135} The situation appears to be similar in humans during prolonged food deprivation.¹³⁶ Thus it has been proposed that at any given time, insulin secretion will be governed not only by the blood glucose concentration, but also by the prevailing concentration and nature of the circulating fatty acids. The exact mechanism by which FFA (or an active form like LCACs) modulate insulin secretory function is not known, but the site of action appears to be at a late step of the insulin secretory process, since it is common to a variety of insulin-secretory stimuli.¹³⁷

The ability of circulating FFA to sustain basal β -cell function in the fasted state and to assure efficient nutrient-stimulated insulin secretion when the fast is terminated must be considered a physiologic phenomenon. In prediabetic obese individuals, basal hyperinsulinemia and exaggerated postprandial insulin secretion are widely accepted as compensatory responses to the preexisting muscle insulin resistance. However, because at this early stage only a small increase in plasma glucose concentration is observed in association with insulin resistance and hyperinsulinemia, it is not clear how the β cells sense peripheral insulin resistance and become hyperresponsive to glucose. An attractive hypothesis is that tissue accumulation of fat plays a role in inducing both muscle insulin resistance and pancreatic glucose hyperresponsiveness.

Both experimental and circumstantial evidence is mounting, however, that chronic exposure to FFA has deleterious effects on insulin secretion. Long-term intravenous infusions of FFA impair insulin secretion in both animals and humans.^{138,139} Elevated FFA plasma concentrations have been found to predict diabetes.^{140,141} In Pima Indians, a high fasting plasma FFA concentration predicted the development of diabetes independently of insulin resistance, but not independently of insulin secretion.¹⁴¹ Results from this prospective study are consistent with the hypothesis of a deleterious effect of chronically elevated FFA concentrations on insulin secretion. Possible mechanisms underlying the "lipotoxic" effects of FFA on the β cell include overproduction of NO,¹⁴² interleukin-1 β ,¹⁴³ and/or ceramide,¹⁴⁴ the latter possibly being responsible for the accelerated apoptosis observed in fat-laden β cells.

OBESITY, T2DM, AND THE AUTONOMIC NERVOUS SYSTEM

Fasting hyperinsulinemia and exaggerated insulin response to glucose are typical characteristics of various animal models of genetic or hypothalamic obesity and diabetes. They include the *ob/ob* mouse, the *fa/fa* rat, and rodents with lesions of the ventromedial hypothalamus.^{145–153} The metabolic abnormalities observed in these animals are thought to be due to an abnormal function of the autonomic nervous system, namely low sympathetic nervous system activity and an exaggerated parasympathetic drive to the pancreas. In humans, the autonomic nervous system is also thought to be involved in the regulation of energy¹⁵⁴ and glucose/insulin metabolism.¹⁵⁵

Studies in Caucasians indicate that the activity of the sympathetic nervous system is related to the three major component energy expenditure: resting metabolic rate,¹⁵⁶ the thermic effect of food,¹⁵⁷ and spontaneous physical activity.¹⁵⁸ We have recently shown that sympathetic nervous system (SNS) activity is also related with daily fat oxidation rates.¹⁵⁹ Further indications of possible role of SNS activity in the regulation of energy balance in humans comes from a study showing that low SNS activity is associated with poor weight loss outcome in obese subjects treated with diet.¹⁶⁰ Furthermore, Pima Indians, who are prone to obesity, have low rates of muscle sympathetic nerve activity compared to weight-matched Caucasians.¹⁵⁶ In a prospective study, baseline urinary excretion rate of norepinephrine, a global index of SNS activity, was negatively correlated with body weight gain in male Pima Indians.¹⁶¹ Thus low activity of the SNS is associated with the development of obesity, which in turn is a risk factor for T2DM.

Parasympathetic, sympathetic, and sensory nerves richly innervate the pancreatic islets. Experimental evidence indicates that insulin secretion is stimulated by parasympathetic nerves and the neurotransmitters and inhibited by sympathetic nerves and the neurotransmitters.^{155,162} The autonomic innervation of the pancreas seems to be of physiologic importance in mediating the cephalic phase of insulin secretion.^{155,163} However, the autonomic nervous system could also be involved in the islet adaptation to insulin resistance with possible implications for the development of T2DM¹⁵⁵ (see Chap. 9).

At the opposite extremes of the relationship between autonomic nervous system activity and insulin secretion, are patients with Prader-Willi syndrome and the Pima Indians of Arizona.^{164,165} Patients with Prader-Willi syndrome, a relatively common form of genetic obesity, who are hypoinsulinemic and have a delayed insulin response to a meal, have a very low parasympathetic drive to the pancreas.¹⁶⁴ Pima Indians seem to have a complex disturbance of the autonomic function, including not only lower sympathetic nervous system activity,¹⁵⁶ but also an increased parasympathetic drive to the pancreas, which is detectable in childhood.¹⁶⁵ This is thought to contribute, at least in part, to the high prevalence of hyperinsulinemia in this population.¹⁶⁶ Of note, fasting hyperinsulinemia has recently been reported to be an independent risk factor for T2DM in the Pimas.¹⁶⁷

OBESITY AND T2DM IN CHILDREN AND ADOLESCENTS

Childhood obesity is a very serious problem because obese children tend to grow into obese adults.¹⁶⁸ Furthermore, duration of obesity is an independent predictor of poor health outcomes.¹⁶⁹ The risk of developing obesity seems to be especially elevated during early infancy, the adiposity rebound period during prepubertal growth, and the adolescent growth phase.¹⁷⁰

The observation that obesity occurs more frequently in children of obese parents has led to a variety of studies to determine how much of the genetic predisposition to obesity is related to energy metabolism. As in adults, some but not all studies have reported that excessive energy intake and/or a low energy expenditure in early childhood increase the risk of obesity later in life.^{171–176} Despite large inconsistencies in the literature and because low levels of aerobic fitness,¹⁷⁷ excessive TV viewing,¹⁷⁸ and limited playing time¹⁷⁹ have all been associated with increased risk

of weight gain, it seems reasonable to conclude that a sedentary lifestyle in early childhood should be discouraged.

One of the most troubling aspects of the current epidemic of obesity is the increasing prevalence of T2DM among children and adolescents.⁴ Until recently, immune-mediated type 1 diabetes was the only type of diabetes considered prevalent among children. Recent reports indicate that 8–45% of children with newly diagnosed diabetes have non-immune-mediated diabetes. While percentages vary greatly depending on ethnicity and sampling strategies, the majority of these children have T2DM.¹⁸⁰

Because the emergence of T2DM in children and adolescents is a relatively recent phenomenon, there is only a limited amount of data on the epidemiology of the disease in the general U.S. population, but it seems that certain ethnic minorities are disproportionately affected.¹⁸¹ Among the Pima Indians of Arizona an analysis performed from 1992 to 1996 revealed a prevalence of T2DM of 2.2% in the 10- to 14-year-old age group and 5% in children 15–19 years of age.¹⁸²

Obesity is the hallmark of T2DM in youth, with up to 85% of affected children being either overweight or obese at diagnosis.¹⁸⁰ Usually a family history of diabetes is also present, with up to 80% of patients having at least one parent and close to 100% of the patients having a first- or second-degree relative with diabetes.^{180,182} Female sex and puberty are other possible risk factors for developing T2DM at an early age.¹⁸⁰ Studies in Pima Indians indicate that offspring of women who had diabetes during pregnancy are especially at risk of T2DM at an early age.¹⁸³ Exposure to the diabetic intrauterine environment was responsible for about 40% of the T2DM seen in children aged 5–19 between 1987 and 1994, approximately twice the attributable risk found between 1967 and 1976.¹⁸³ It remains to be seen whether gestational diabetes is a factor in the alarming rise of T2DM seen in youth nationally.

SUMMARY AND CONCLUSION

Obesity is a chronic disease that is quickly reaching epidemic proportions, and one that increases the risk for other noncommunicable diseases, and thus reduces life expectancy. Obesity is heritable and it results from a chronic imbalance between energy intake and energy expenditure. However, its exact etiology is unknown.

While it is often observed in association with T2DM, obesity is neither necessary nor sufficient alone to cause T2DM. In some predisposed individuals and populations, obesity substantially increases the risk of developing T2DM by lowering insulin sensitivity, and possibly by increasing insulin secretory dysfunction. The precise links between obesity and T2DM have yet to be unequivocally identified.

In conclusion, further research is needed to understand the etiology of obesity and how obesity precipitates the development of T2DM in predisposed individuals.

Aging and Diabetes

Robert V. Hogikyan

Jeffrey B. Halter

CLASSIFICATION AND DEFINITION

The American Diabetes Association (ADA) criteria for diabetes and impaired glucose tolerance, provided in Chap. 8, are currently applied to adults of any age, despite the fact that glucose tolerance is known to deteriorate with age. However, as discussed later in this chapter, the increased likelihood of intercurrent illness and medication use in an older adult needs to be taken into account when interpreting any serum glucose level in an older person.

Older persons with diabetes are a heterogeneous group. While 90% have type 2 diabetes mellitus (T2DM), these individuals may vary from lean to obese, from good general health to having multiple comorbid conditions, and from being fully functional to having major functional disabilities. They may be treated with diet, oral hypoglycemic agents, insulin, or a combination of these approaches. Some older adults may initially appear to have typical T2DM and have significant residual β -cell function at the time of diagnosis, but then progress with time to insulin dependency. This progression may take months to years before an insulin-deficient state develops. Rarely, an older person may present with classical autoimmune type 1 diabetes. Others with type 1 diabetes mellitus (T1DM) survive until old age and become part of the heterogeneous population of elderly diabetic patients. This heterogeneity must be taken into account when deciding about treatment goals and interventions for a given elderly patient.

EPIDEMIOLOGY

Diabetes mellitus is a very common health problem among older adults. Nearly half of all patients with T2DM are aged 65 years or older.^{1,2} The proportion of the U.S. population meeting current ADA criteria increases dramatically with advancing age through at least the mid-70s (Fig. 24-1), but many are undiagnosed.³ Some older diabetes patients are first identified by screening fasting plasma glucose (FPG) levels. Oral glucose tolerance tests (OGTTs) identify others who do not have elevated FPG but meet the diabetes criterion of a 2-hour OGTT glucose level ≥ 200 mg/dL, a situation known as isolated postchallenge hyperglycemia (IPH). IPH increases dramatically with advancing age¹⁻³ and has raised problems due to the recent focus on use of fasting glucose levels to make the diagnosis. The overall total prevalence of diabetes in people aged 60–74 years is 26%, a rate ten times greater than that seen in people under age 40.¹ The high prevalence rate of diabetes per-

sists in populations 70 years of age and older. In addition to the high prevalence of diabetes in older adults, 14% of the U.S. population over age 60 meet the ADA criteria for impaired fasting glucose (IFG) and 20% meet the criteria for impaired glucose tolerance (IGT). Ethnic differences in rates of diabetes appear to apply to elderly populations as well, with higher rates in older Hispanic and African-American adults than in Caucasians.⁴

While identifying individuals with diabetes in order to initiate treatment early is clearly a priority, to be able to protect individuals from developing diabetes could also be worthwhile. Total expenditure of energy during leisure time appears to protect against the development of type 2 diabetes independent of age, obesity, history of hypertension, or parental history of diabetes.^{5,6} This protective effect was not limited to intensive exercise, which may be less sustainable into older age. Recent findings indicate that lifestyle intervention including diet and exercise can delay progression from IGT to diabetes in middle-aged and older adults.⁷

Given that people over age 85 are the fastest growing segment of the population, there is significant growth expected in the population living in institutional long-term care settings. Those living in an institutional long-term care setting may carry a diagnosis of diabetes, and there may be special considerations in the treatment of diabetes in this population. However, the epidemiology of diabetes in this population has not been adequately studied.

Older adults with T2DM are at increased risk for all of the long-term diabetes complications,⁸ as summarized in Table 24-1. Observational studies suggest that poor glycemic control in older people with diabetes contributes to excessive risk of stroke and cardiovascular events.^{9,10} Atherosclerotic macrovascular disease accounts for 75% of the mortality among people with diabetes in the U.S.¹¹ Increased risk for cardiovascular disease is also associated with IGT, in the absence of overt diabetes.^{12,13} Diabetes is the major cause of renal failure and dialysis in people over 65 in the U.S.¹⁴ The risks of end-stage renal disease, loss of vision, myocardial infarction, stroke, and peripheral vascular disease increase with age in the absence of diabetes, but these risks in elderly patients with diabetes are even greater (Table 24-1). Because diabetes complications are generally viewed as long term, it could be argued that such complications are not of concern in someone who is already very old. However, even a new diagnosis of diabetes in an older person may be preceded by an unknown period of undetected hyperglycemia. In addition, the average remaining life expectancy for a 65-year-old person is nearly 20 years, and for a 75-year-old person over 10 years.¹⁵

FIGURE 24-1. Prevalence of type 2 diabetes among elderly people according to age and ADA diagnostic criteria (NHANES III). FPG, fasting plasma glucose; OGTT, oral glucose tolerance test; IPH, isolated postchallenge hyperglycemia. (Adapted from Harris et al.¹ and Resnick et al.²)

Diabetic retinopathy is a major cause of visual loss in older adults, and even if it does not lead to blindness is associated with disability and depression.^{16,17} Peripheral neuropathy, due both to micro- and macrovascular disease, and peripheral vascular disease are particularly prevalent in older age groups. Amputations increase with age, as do balance problems, mobility impairment, and chronic pain related to diabetic nerve disorders.¹⁸ Diabetic neuropathy is common in this population, but the epidemiology is not yet sufficiently defined to establish the degree of increased risk.

MECHANISMS FOR AGE-RELATED CHANGES OF CARBOHYDRATE METABOLISM

Studies of the effects of aging on carbohydrate metabolism have been reviewed.¹⁹ A major challenge to the interpretation of age-related differences in measures of glucose metabolism is that glucose metabolism is sensitive to a wide range of factors. Thus it may be very difficult to specifically define effects of aging that are independent of other factors. As summarized in Fig. 24-2, it is likely that there are primary changes in pancreatic β -cell function and possibly changes in insulin action with aging that contribute to age-related changes in glucose metabolism. It is also likely that there are specific genetic factors that may influence the expression of glucose intolerance with aging, although such genetic factors have yet to be defined. Several studies have attempted to control for the other variables that may affect glucose metabolism in studies of human aging. Although there are exceptions, these studies suggest

FIGURE 24-2. A summary of factors that may contribute to the high rate of diabetes mellitus and impaired glucose tolerance among older adults. (Reproduced with permission from Diabetes Update: Elderly Patients with Non-Insulin Dependent Diabetes Mellitus. The Upjohn Company, 1990.)

that there is a gradual decline in glucose tolerance with age, both in healthy men and women, but that this age effect is relatively modest in magnitude. Glucose intolerance occurs in older people accompanied by delayed absorption of oral glucose and delayed post-hepatic glucose delivery. Greater hyperglycemia in older people results from delayed suppression of hepatic glucose output and a decreased rate of peripheral glucose uptake following oral glucose ingestion.²⁰

Many studies have been carried out to assess the effects of aging on insulin secretion in experimental animals and in humans. A delayed insulin response during an OGTT has been observed in some studies. OGTT and hyperglycemic glucose clamp studies suggest that gross impairment of pancreatic β -cell function is not characteristic of normal human aging.^{19,21} However, clear age-related pancreatic β -cell functional deficits have been demonstrated in pulsatile insulin secretion²² and with quantitation of the potentiating effect of glucose on insulin secretory responses to a nonglucose stimulus such as the amino acid arginine.^{19,23}

A problem in the interpretation of studies of pancreatic β -cell function in aging is the confounding effect of coexistent obesity and insulin resistance in elderly people. As described below, a number of studies have provided evidence for the presence of insulin resistance in elderly humans.¹⁹ The normal physiologic feedback control mechanism for regulation of glucose homeostasis should result in hyperinsulinemia to compensate for the presence of insulin resistance if pancreatic β -cell function is completely normal. Thus the finding of similar pancreatic β -cell responses to glucose challenge in old and young subjects may in fact represent a relative impairment in β -cell function among the older subjects if they are also insulin resistant. When the confounding effects of obesity, insulin resistance, and age-related declines in insulin clearance have been taken into account, diminished pancreatic β -cell function is observed in older humans.²³⁻²⁶

Many studies have demonstrated resistance to the metabolic effects of insulin in aging animals and humans (see reference 19 for review). Age-related deficits in postreceptor insulin signaling have been observed in fat, muscle, and liver. Increased adiposity is one factor that contributes to age-related alterations in insulin ac-

TABLE 24-1. Important Long-Term Complications of Diabetes in Older Adults and Their Relative Risk*

†Relative risk for blindness.

tion. Several studies of age group differences in humans have attempted to control for the influence of adiposity by including a large sample size and multiple measurements of various aspects of body fat mass and distribution. Although all of these studies are not in full agreement, overall they suggest that there is a persistent effect of age on both glucose tolerance and insulin action that is independent of body fat mass and distribution in humans.²⁷⁻²⁹ However, there is heterogeneity among the elderly population. Older people who have been selected to meet criteria for normal glucose tolerance are less obese with less central adiposity, and did not have a detectable decrease of insulin sensitivity^{30,31} independent of obesity.

Aging-associated decreased mobility and diminished physical activity may also contribute to age-related changes in glucose homeostasis. Healthy older men with greater degrees of physical fitness, usually as assessed by measurement of maximal oxygen uptake during exercise, have better glucose tolerance and less evidence of insulin resistance than less active older adults.^{19,28} More physically fit elderly people also tend to have less body fat and less central adiposity. While some glucose intolerance appears to persist with age even when controlling for these factors, the age-related change is modest.

A significant improvement in insulin action has been demonstrated in older adults following exercise training.³²⁻³⁴ The reduction of insulin resistance accompanying exercise training under these circumstances is associated with diminished pancreatic β -cell responses to stimulation,³² as would be expected from the physiology of the feedback control system affecting glucose and insulin. This compensation may explain why the improvement of insulin action associated with exercise training has generally not affected overall glucose tolerance.

Some groups of people with essential hypertension have associated insulin resistance and glucose intolerance.³⁵ Given the high prevalence of hypertension among the elderly population, blood pressure may be an important variable when trying to understand age-related glucose intolerance. However, the degree of association between insulin resistance or hyperinsulinemia and hypertension has varied considerably in different studies, perhaps related to the degree of obesity and the pathophysiology of hypertension in the populations.^{36,37} In the predominantly Caucasian population of the Baltimore Longitudinal Study of Aging, little if any relationship between hyperinsulinemia and blood pressure was found after adjusting for other variables.³⁸

A number of pharmacologic agents in common use have known effects on glucose metabolism. Since older adults are frequent users of pharmacologic agents, interpretation of alterations of glucose metabolism in such individuals must take into account drugs that they are using. Table 24-2 includes a list of some of the drugs that are known to affect glucose metabolism. Because of the association of hypertension with insulin resistance and glucose intolerance as described previously, effects of antihypertensive agents on glucose metabolism have been of particular interest. Though none of the drug effects on glucose metabolism seem to be of large magnitude, a variety of adverse effects have been documented.³⁹

INITIAL PRESENTATION OF THE OLDER PATIENT WITH DIABETES

Type 2 diabetes is frequently asymptomatic in older adults. When signs or symptoms are present, they may be difficult to interpret in

Pentamidine
Nicotinic acid

older people. The atypical presenting symptom or sign may be misinterpreted as the consequence of an illness other than diabetes, or may be fully attributed to a condition other than diabetes, when in fact diabetes is in part responsible for the sign or symptom. One such presenting sign may be unexplained weight loss. While a number of etiologies such as malignancy need to be considered, substantial weight loss can occur in an older person with marginal oral intake in the setting of poorly controlled diabetes. Other atypical symptoms in an older person with poorly controlled hyperglycemia include generalized weakness or malaise, anorexia, and confusion.

With the expanded use of blood chemistry screening, the presence of hyperglycemia is readily established. More challenging is the interpretation of an elevated random serum glucose in an older person. One example is the acutely ill hospitalized older person who is physiologically stressed. Known interactions between stress hormones, insulin secretion, and insulin sensitivity will acutely elevate the serum glucose, which may return to a normal range upon resolution of the acute stress.⁴⁰ As summarized in Table 24-2, medication use may also complicate the interpretation of hyperglycemia in an older person, as there is an increased likelihood of use of multiple medications.

Urinary incontinence may be confused with hyperglycemia-related polyuria. The insensate neuropathic bladder with overflow incontinence may be a sign indicating diabetes presenting as neuropathy. Urinary frequency may be attributed to prostatic hypertrophy, urinary tract infection, or diuretic therapy, when in fact these problems are only contributing causes and hyperglycemia is a major problem for the patient.

Since thirst perception may be altered in older people, polydipsia may not occur in response to the increase of osmolality associated with hyperglycemia. Even when thirst is appreciated by the patient, access to water or other fluids may be limited, especially for the older patient with functional dependence on others. Intravascular fluid depletion and orthostatic hypotension may result, and the patient may present with a history of falling or hyperosmolar coma.

COMPREHENSIVE ASSESSMENT OF THE OLDER ADULT WITH DIABETES

Medical care of a geriatric patient should begin with a comprehensive geriatric assessment. A comprehensive geriatric assessment is a multidisciplinary evaluation in which the multiple problems of

older persons are uncovered, described, and explained, if possible, and in which the resources and strengths of the person are catalogued, need for services assessed, and a coordinated care plan developed.⁴¹ In this section, consideration will be given to some of the physical, mental, social, economic, functional, and environmental domains requiring special attention.⁴¹

Functional Status

The functional assessment of geriatric patients is a critical component of a comprehensive geriatric assessment, and is recommended for all older patients.⁴² Older adults with diabetes are about two to three times more likely to have physical limitations⁴³ and 1.5 times more likely to have decrements in activities of daily living (ADL) than those without. Much of this excess disability is a direct result of complications of diabetes, such as eye disease, increased strokes and cardiovascular disease, and increased neuropathy and peripheral vascular disease.⁴³ The assessment of functional status can begin prior to the physician-patient encounter with a self- or family-completed questionnaire. ADL can be further assessed during the history and physical examination. It is important that the patient's family or caregiver assist in completing this assessment.

Cognitive Function

The older patient with diabetes, like all patients with diabetes, will need to maintain control over a variety of aspects of day-to-day life that may affect glucose regulation. Maintaining a proper diet, medication administration, and skin care, for example, require cognitive skills and reliable memory function. A number of age-related deficits in cognition and memory function have been identified, but there is a great deal of variability in how an individual's memory and cognition may change. Older individuals will perform tasks requiring retrieval of newly-learned material from secondary memory less well than younger individuals. Older persons will also perform less well when the process requires carrying out two tasks concurrently. However, these changes have little effect on ADL.

When compared with age-matched controls, older subjects with T2DM who do not have evidence of a coexisting cognitive disorder perform more slowly and less well on complex tasks.⁴⁴ No differences were observed between type 2 diabetics and controls in the areas of basic attentional processes, short-term memory, and semantic memory.⁴⁵ However, these deficits are relatively minor in older people who do not have central nervous system (CNS) pathology. Of much greater potential impact in an older person with diabetes is coexistence of a major cognitive disorder. The prevalence rate of cerebrovascular disease is high in the diabetic older population. Alzheimer's disease is common and may coexist, although it is uncertain whether the prevalence is higher or lower in people with diabetes.^{44,46} Therefore cognition and memory function need evaluation in the comprehensive assessment of an older patient with diabetes. The possible presence of deficits in the performance of complex tasks, speed and memory tasks, serial learning tasks, and primary CNS pathology need to be assessed. Speed of processing and memory function may have implications for activities such as driving, where a problem may not otherwise be brought to light until there is an accident. There are a number of good screening instruments which have been shown to be valid and reproducible in older adults.⁴⁷ These can be administered quickly and highlight deficits. When the deficits are less clear, the performance of more complete neuropsychological testing may be indicated.

Psychosocial Situation

With the growing complexity of our day-to-day lives, there may be less availability of the extended family, putting many elderly people with diabetes at risk for psychosocial difficulties. The older individual's health can affect their self-esteem, recreational activities, social contacts, and family relationships, including contact with younger family members. Since the older patient with diabetes and no informal system of support may be at high risk for functional decline, delivering quality care can be a substantial challenge. When health care is compromised by the home situation, entry into an assisted living situation or other institutionalization must be considered.

Diet Maintenance and Access to Food

One of the cornerstones of working with a patient with diabetes is assuring that the patient maintains a proper diet. Specific recommendations with regard to nutrition and diet for patients with diabetes are presented in Chap. 26. In the older patient with diabetes there are some areas of special concern which need to be considered, as summarized in Table 24-3. Nutritional needs of elderly patients may differ due to a number of factors. Physiologic alterations include a decrease in energy needs due to decreased activity. Some may experience declining health status, including increased prevalence of chronic disease with poor nutrition, depression, dementia, medication-induced anorexia, or feeding dependency. In addition, some may be socially isolated, possibly due to the loss of a spouse, and find eating alone a problem.

Although there is little research in the area, no specific modifications in the diet currently recommended by the ADA are suggested for older adults with diabetes. Functional ability and financial considerations are important areas that need assessment in the older patient with diabetes. In those patients with reduced food access, a network of formal and/or informal support services may be available to assist them and needs to be explored. For those community-dwelling older adults with diabetes and limited access to food, home delivered meals may enhance the likelihood of following a diabetic diet and reduce "food insecurity" (concern about obtaining and preparing food), as well as decrease the frequency of being hospitalized for hyper- or hypoglycemia.⁴⁸ A program of home delivered meals is available in many communities and should be considered a valuable resource. This problem of access to proper diet may exist among residents of long-term care facilities. Thus residents who are dependent on staff for feeding are at significant risk for inadequate dietary intake.

TABLE 24-3. Dietary Therapy: Special Considerations for Older Adults with Diabetes

Access to food
Functional disability
Poor meal preparation skills
Lack of formal and/or informal support to obtain food
Limited financial resources
Food intake
Decline in taste and smell appreciation
Poor dentition and/or xerostomia
Ingrained dietary habits
Past experience and ethnic food preferences
Impaired cognitive function

Assuming food is available, intake may be reduced because of an age-associated decrease in the ability to appreciate taste and smell. To the extent that taste influences dietary intake, decreased taste may be a contributor to the decreased caloric intake which has been reported among older humans. A decline in physical activity, particularly common among older people with diabetes,^{49,50} may also play a role in this decreased caloric intake.

In the institutional long-term care setting, inappropriate or absent dietary prescriptions are sometimes found.⁵¹ Particularly in an institutional long-term care setting, weight maintenance as a goal of therapy may be more important for older patients than weight reduction, since low body weight and undernutrition may be more prevalent than obesity in this setting. A careful nutritional assessment on a regular basis of the institutionalized older adult with diabetes is very important in guiding the dietary prescription.

Adequacy of food intake may also be affected by oral health problems in older patients. Tooth loss is common in the older adult population, and severe tooth loss limits the foods that are considered acceptable. Thus for geriatric patients with diabetes who may already be struggling to identify foods that meet their dietary needs, tooth loss may further limit their choices. Another concern of many older patients with diabetes is dry mouth. It is not clear if diabetes *per se* increases the likelihood of xerostomia, but xerostomia is common in this population and associated with use of multiple medications.

Vision Problems Including Cataracts and Retinopathy

For the older patient with diabetes who may already have functional deficits, loss of sight may be devastating. Thus proliferative retinopathy with possible hemorrhage into the vitreous or macular edema are manifestations with potentially disastrous results. Many older people with diabetes do not comply with the ADA recommendation that patients with diabetes have a yearly dilated ophthalmoscopic examination.⁵² Some of the responsibility for not having annual examinations rests with health care providers who fail to refer patients for examination. The percentage of patients who do not undergo annual dilated examinations may be even higher among institutionalized elderly people with diabetes.

Cataracts, macular degeneration, and glaucoma also place the older patient with diabetes at increased risk of blindness. Cataracts are the most common age-related ocular disorder, and subjects with diabetes have a higher rate than those without diabetes. Performance of regular ophthalmologic examinations in the older patient with diabetes, given the potential for other functional deficits, is at least as important as in a younger patient with diabetes.

Urinary Continence

Urinary incontinence is common both among community-dwelling elderly people (10–43%) and among those living in institutional long-term care settings (36–62%).⁵³ Changes in bladder function are very common in patients with diabetes and are characterized by some as “diabetic cystopathy.” The noteworthy clinical feature of bladder involvement in diabetes is the insidious onset and progression of bladder paresis, eventually leading to retention. Urinary retention with overflow incontinence represents one of the major causes of urinary incontinence in geriatric patients.

In one study in an institutional long-term care setting, involuntary bladder contractions were the presumed contributor to urinary

incontinence among 61% of the older patients with diabetes. All patients with urinary retention had poor or no bladder contractions. While diabetic cystopathy is one factor contributing to urinary incontinence in this population, older patients with diabetes are at risk for the other common causes of urinary incontinence: detrusor overactivity, outlet incompetence, outlet obstruction, and detrusor underactivity. In the patient who is functionally dependent on others for assistance in transferring from bed to wheelchair or wheelchair to toilet, urinary incontinence may be termed environmental when the necessary assistance is not available. The evaluation of an older adult with diabetes for urinary incontinence should follow guidelines for the evaluation of any older adult with urinary incontinence.⁵⁴ These guidelines differ for community-dwelling elderly as compared with those living in an institutional long-term care setting.

Sexual Function and Dysfunction

Sexual activity can persist well into older adulthood, although there is a general decrease with age. In a survey of 225 elderly male veterans in a geriatric ambulatory care clinic 47% of those aged >75 years reported absent libido.⁵⁵ Overall this study found sexual dysfunction to be related to subjective poor health, diabetes, and incontinence. At present little information is available about sexual function in older women with diabetes.

By virtue of age, older men and women are at risk for social factors contributing to decreased sexuality. Three social factors contribute to whether an older patient remains sexually active. First, a patient must feel the desire to do so; second, they must have access to a sexually functional partner; and third, they must have access to an environment with privacy. Chronic diseases, simple demographics, and living with children or in an institutional long-term care setting contribute to these social factors.

Polypharmacy and Drug Interactions

The older patient with diabetes is likely to have a number of other chronic medical conditions which are treated with medications. The number of medications prescribed for older patients increases with increasing age, both in inpatient and outpatient settings. One of the major concerns with the increased number of prescriptions per patient is the risk of adverse drug reactions, since the percentage of patients with adverse drug reactions increases exponentially with the number of medications taken. Elderly patients with diabetes are at increased risk for adverse drug reactions for a variety of reasons: age-related alterations of pharmacokinetics and in some cases pharmacodynamics; decreased vision and cognition; peripheral diabetic neuropathy and coexisting arthritis making childproof lids unusable; and as mentioned above, the greater likelihood that elderly patients are taking multiple medications. Effective methods for reducing polypharmacy and improving prescription of medications have been demonstrated in both the outpatient and institutional long-term care settings,^{56,57} and explicit criteria have been developed to identify inappropriate medication use in the institutional long-term care setting.⁵⁸

APPROACHES TO THERAPY

The comprehensive geriatric assessment should provide the information needed to decide upon a therapeutic approach to the older patient with diabetes. Such information includes current general

health, remaining life expectancy, motivation and commitment of the patient and family, finances, and support services. All of these factors can have a significant impact on the treatment approach.

Management of Atherosclerotic Risks and Complications

Reduction in risk factors for atherosclerotic disease is a major goal of diabetes management in older adults. A high proportion of older diabetes patients have associated hypertension, hyperlipidemia, and atherosclerotic arterial disease.^{59–62} Although fewer older people smoke cigarettes, smoking cessation programs should be encouraged for those who do. Older diabetes patients have been shown to benefit as much or more than nondiabetes patients from hypertension treatment.^{63,64} Aspirin use is beneficial in older patients with diabetes and atherosclerosis risk or atherosclerosis.⁶⁵ Treatment of hyperlipidemia in diabetes patients with cardiovascular disease has been shown to be beneficial and may decrease mortality in those who may develop cardiovascular disease; no age limit has been defined, although there are limited data available for people over age 75. Peripheral vascular occlusive disease and amputations increase with age, so monitoring and evaluation for circulatory problems is indicated. Preventative treatment and monitoring for complications is not just for those older patients who are seriously ill or have advanced dementia. Most older people, even those with comorbidities and disability, will benefit from interventions shown to prevent or slow an increasing burden of illness over a period of several years.

Management of Microvascular Risks and Complications

Treatment with an ACE inhibitor and aggressive management of hypertension and hyperglycemia are the major recommended interventions for preventing end-stage renal disease due to diabetes.¹⁴ These interventions are appropriate for the majority of older diabetes patients. Peripheral neuropathy leading to pain, neuropathic joints, wounds, mobility problems, and amputations contribute to disability and poor quality of life in older patients. The little evidence that is available suggests that foot care and monitoring may be associated with better outcomes.

Yearly retinal examinations and intervention as appropriate are recommended for older people with diabetes. Although simulations have suggested that few older persons with late-onset diabetes are likely to go blind due to diabetes,⁶⁶ it is important to remember that most older people do not have late-onset diabetes; many have had diabetes for 10 years or more and the true duration of diabetes is not known for many others.

Treatment of Hyperglycemia

There are two general approaches to treatment of hyperglycemia in this group of patients: basic care and intensive care. When the goal is primarily the prevention of symptoms of hyperglycemia, a basic care approach is sufficient. The alternative is intensive care when treatment is aimed at achieving ADA guidelines for glucose levels as close to euglycemia as possible with the goal of preventing the long-term complications of diabetes. Unfortunately, as in other patient groups, only a minority of older people with diabetes achieve recommended goals for treatment of hyperglycemia,^{3,67,68} as illustrated in Fig. 24-3. Nonpharmacologic treatment, oral hypoglycemic agents, and insulin therapy can each play a role in the

FIGURE 24-3. Percentage of patients in NHANES III who did not achieve the level of hemoglobin A_{1c} (HbA_{1c}) recommended by the American Diabetes Association (HbA_{1c} < 7%). Patients were analyzed by age group and according to whether their HbA_{1c} was in the range at which the ADA recommends therapeutic action (>8%) or not (7–8%). (Adapted from Shorr RI, et al., 2000⁶⁷).

management of the older adult with diabetes, whether the treatment goal is control of symptoms of hyperglycemia or achievement of euglycemia.

The prevention of symptomatic hyperglycemia by delivering basic care includes the prevention of glycosuria and associated intravascular volume depletion. Glycosuria may result in urinary incontinence, and intravascular depletion may result in hyperglycemic hyperosmolar nonketotic coma, the most severe acute complication of diabetes in an older adult. Glycosuria may also result in weight loss due to calorie loss in the urine. The resultant catabolic state can lead to excess protein breakdown and the loss of lean body tissue. The goal of prevention of symptoms of hyperglycemia can be accomplished and glycosuria minimized by maintaining a serum glucose averaging about 200 mg/dL.

The decision about goals of treatment in the older adult with diabetes is critical to planning the management of hyperglycemia in an individual patient. This decision may be made with the patient alone. However, when comprehensive geriatric assessment indicates that the patient may need assistance, others may need to be involved in the decisionmaking process. A primary caregiver or other responsible party along with consultants may be needed to clarify the patient's condition.

Education

Education is an important component in the management of an older patient with diabetes. Short-term diabetes education program sessions can increase patient knowledge, reduce stress, improve diet, and enhance quality of life. When a spouse is involved there is greater improvement in knowledge, less patient stress and better glycemic control.⁶⁹ The Colorado Diabetes Control Program was able to document an improved level of patient care and a significantly reduced length of hospital stay for patients with diabetes who were admitted to an acute care hospital following a 2-year educational intervention. Care of the older adult with diabetes in an institutional long-term care setting can be made easier and may be more effective with an educational intervention aimed at the patient care staff.

Diet

Dietary therapy is a basic building block of therapy for the older adult with diabetes. There is no evidence to suggest that dietary therapy is more or less effective in older adults with diabetes than younger ones. Dietary restriction and weight loss should help the older adult with diabetes achieve better control of the hyper-

glycemia, but caution is indicated. If functional restrictions prevent the older adult with diabetes from increasing caloric expenditure during dietary restriction, weight loss may be more difficult to achieve. In this situation, caloric restriction sufficient to cause weight reduction may be severe enough to put the patient at risk for nutrient or vitamin deficiencies, thereby potentially exacerbating functional limitations by reducing muscle strength.

The general dietary recommendations for patients with diabetes are discussed in Chap. 26. There are no specific alterations to the recommended diet for treatment of older adults, but there is a lack of studies in the area. The ability of an older adult with diabetes to follow a therapeutic diet may be limited by circumstances discussed earlier, such as physical limitations in obtaining food, financial limitations, alterations in taste and smell, and ingrained lifelong dietary habits which may be further complicated by ethnic food preferences. A dietician experienced in working with older adults can be of great help.

Exercise

The beneficial effect of progressive resistance exercise on muscle strength and function is clear even among the elderly.⁷⁰ Exercise would be expected to result in improved physical functioning in resistance-trained older adults with type 2 diabetes. As summarized in Table 24-4, in addition to improved physical functioning, benefits of exercise may be in two areas: direct effects on glucose metabolism, and effects on other common comorbidities in patients with T2DM. Although large-scale studies in older adults with T2DM are not yet available, lower fasting plasma glucose and glycosylated hemoglobin, improved oral and intravenous glucose tolerance, and enhancement of insulin action may be seen in older adults with T2DM on a regular exercise program.⁷¹

Exercise may also offer substantial reduction of risk for the development of cardiovascular disease. However, there are also some potential problems and risks in prescribing exercise for an older adult with diabetes. One study found that 81% of a population of older men with newly diagnosed diabetes were unable to participate in an exercise program due to medical treatment or comorbid diseases.⁷² Despite the potential benefits of exercise in the older adult with diabetes, it may not be prescribed by health care providers. For example, highly experienced nurse providers of

health care to older adults with diabetes reported not teaching clients about exercise. This was due to lack of resources, lack of specific knowledge about exercise, and a negative perception about their patients' ability to exercise.⁷³ The general approach to the use of exercise in patients with diabetes is discussed in Chap. 27.

Pharmacologic Intervention

There are some special considerations in the older adult with diabetes when nonpharmacologic treatment has been unsuccessful in controlling glucose levels and the addition of an oral hypoglycemic agent or insulin is being considered. Of these the risk of hypoglycemia is the most serious.

Oral Hypoglycemic Agents

The efficacy and mechanism of action of oral hypoglycemic agents are discussed in detail in Chap. 32. There are no data to suggest that the efficacy or mechanism of action of these drugs are different in the older adult with diabetes than in younger patients. Safety and efficacy studies of all the newer agents have included older adults. Studies of combination oral agent therapy have also included older patients and have demonstrated both safety and efficacy.⁷⁴⁻⁷⁶ Although the rate of severe hypoglycemia appears to be low in older people with diabetes, age is an independent risk factor for hypoglycemia during oral agent therapy.⁷⁷ This may be related in part to an age-associated decrease in hepatic oxidative metabolism. Combined with the apparent decrease in hepatic blood flow with age, the metabolism of some oral agents may decline in older patients with diabetes, requiring use of lower dosages. The decline of renal function with age may prolong the duration of action of oral hypoglycemic agents excreted by the kidneys.

The presence of coexisting disease may decrease serum albumin in an older patient, thereby influencing bioavailability of drugs that are protein-bound. Polypharmacy and the potential for drug-drug interactions need to be taken into account when prescribing oral hypoglycemic agents for the older adult with diabetes. Though each medication should be reviewed for potential interaction with the oral hypoglycemic agent being used, there are some general classes of medications that may increase the risk for hypoglycemia: β -adrenergic blockers, salicylates, warfarin, sulfonamides, and alcohol. The longer acting sulfonylureas are reported to cause the greatest number of hypoglycemic episodes in older adults, including prolonged hypoglycemia.⁷⁸

Insulin

The use of insulin therapy can be as appropriate in the older adult with diabetes as in a younger individual. Failure of maximal oral hypoglycemic therapy to achieve the treatment goal is the most common reason to consider insulin therapy in the older adult with diabetes. No studies have shown that insulin therapy is any less effective or more risky in older adults with diabetes than in the young. When the treatment goal is control of symptomatic hyperglycemia, a single daily dose of insulin may be adequate. However, when the goal is euglycemia, a split regimen of mixed insulin will likely be necessary and is tolerated well by older adults.⁷⁹ No special insulin regimens have been identified as more or less efficacious in treating older adults (see Chap. 30 for intensive insulin therapy recommendations in T2DM).

There are some special considerations when prescribing insulin therapy for an older adult with diabetes. A comprehensive geriatric assessment of the older adult with diabetes as discussed earlier in this chapter should identify which, if any, of these special

TABLE 24-4. Potential Benefits and Risks of Exercise for Older Adults with Diabetes

Benefits	Risks
<i>Diabetes-Related</i>	<i>Diabetes-Related</i>
Improved glucose tolerance and increased insulin sensitivity	Hypoglycemia, exercise-induced and delayed
Decreased central and overall adiposity	
<i>General Health</i>	<i>General Health</i>
Increased maximal oxygen consumption	Sudden cardiac death
Decreased blood pressure	Musculoskeletal injuries
Improved physical function and increased muscle strength	
Improved lipid profile	
Increased bone mineral content	
Improved self-image	

considerations apply to each patient. Coexisting conditions commonly found in older adults combined with complications secondary to diabetes may impair the visual, fine motor, cognitive and/or sensory skills necessary for the delivery of insulin therapy and home blood glucose monitoring. Home blood glucose monitoring is important for any older patient treated with insulin.

Hypoglycemia

Since older people with diabetes mellitus receiving pharmacologic treatment are at risk for hypoglycemia, information about hypoglycemia recognition, prevention, and management should be part of their diabetes education program. Studies of hypoglycemia counterregulation under controlled conditions in carefully defined populations of normal older adults and older adults with T2DM have demonstrated some subtle alterations of neuroendocrine function,⁸⁰⁻⁸² but these are unlikely to be of sufficient magnitude to limit the ability to counterregulate hypoglycemia. Effects of hypoglycemia on autonomic symptoms and cognitive function are also minimal in such patients, although a mild impairment of reaction times during hypoglycemia has been observed in older type 2 diabetes patients.⁸¹

Thus otherwise healthy older adults can tolerate hypoglycemia reasonably well and mount an appropriate counterregulatory response. However, older patients with coexisting conditions may have greater risk. Older diabetic patients with autonomic neuropathy or with other neurologic disorders that affect autonomic nervous system function may be less able to counterregulate appropriately, or may develop symptoms requiring corrective action. While many antihypertensive drugs affect autonomic nervous system function and could therefore interfere with counterregulation of hypoglycemia, no increased risk of severe hypoglycemia was observed with antihypertensive drug use in a population study.⁸³

Older individuals with a significant cognitive disorder, poor or irregular nutrition, or those who are prescribed sedating agents or frequently use alcohol may be unable to recognize symptoms of hypoglycemia, or may have an impaired ability to initiate the feeding response to hypoglycemia. The presence of coexisting kidney or liver dysfunction in an older person contributes to the risk of hypoglycemia by reducing the clearance of insulin or oral hypoglycemic agents. The concomitant use of other medications may contribute to increased risk for hypoglycemia or impaired counterregulation in such individuals. The social setting of the patient may also increase the risk for severe hypoglycemia or its sequelae. Thus the identification of risk factors for hypoglycemia should be part of the comprehensive geriatric evaluation.

Older Patients in Institutionalized Long-Term Care

Diabetes is prevalent among the institutionalized long-term care population. Since life expectancy is limited for many patients admitted to long-term care institutions, basic diabetes care aimed at controlling symptoms of hyperglycemia is often the appropriate goal. Maintenance of good nutrition is important for institutionalized patients. Each patient should be assessed by a dietician at the time of admission and on a regular basis thereafter, because aggressive nutritional support may be needed to treat or avoid malnutrition. For the minority of institutionalized patients who are overweight, it may be necessary to decrease their caloric intake. For patients receiving pharmacologic therapy, dosage reduction at the time of admission should be considered to prevent hypoglycemia, because the resident may receive all scheduled medications and a tightly controlled institutional diet. Thus a regimen which may

have appeared inadequate at home due to poor patient compliance may be more effective in the institutional setting.

A frail institutionalized older adult with diabetes may benefit from an exercise program that reduces physical disability,⁸⁴ even if the exercise program is not sufficient to affect glucose levels. Consideration should be given for an exercise program for each patient and the final decision based on information from all appropriate practitioners of the institution's multidisciplinary assessment team.

With regard to pharmacologic treatment, oral hypoglycemic agents or a single dose of mixed insulin will often be adequate to achieve the basic treatment goal of preventing symptomatic hyperglycemia. Insulin will be required in some patients when there is an intolerance or contraindication to oral hypoglycemics, such as acute medical illness or renal or hepatic insufficiency. The monitoring of fingerstick glucose levels by staff in this setting can be a significant aid to the treating physician.

Older Patients in the Acute Care Hospital

The management of diabetes in the hospitalized older adult is, with a few precautions, not very different from managing diabetes in a hospitalized younger adult. The major precautions include an awareness that functional, cognitive, and pharmacokinetic or pharmacodynamic changes may place older patients at increased risk for complications. Therapy for the older patient with diabetes during an acute care hospital admission should emphasize delivering an adequate amount of insulin to prevent the patient from becoming catabolic. To maintain adequate glucose control, some hospitalized older patients with diabetes may need to have insulin added temporarily, despite being adequately controlled at home on diet or oral agents. Therapy needs to be monitored closely to avoid hypoglycemia. Management of hyperosmolar, hyperglycemic nonketotic coma, which occurs primarily in older adults, is discussed in Chap. 35. It emphasizes the importance of fluid and electrolyte replacement, provision of insulin, and treatment of the underlying major illness which is usually present.

Diabetes Secondary to Endocrinopathies

Om P. Ganda

Eric S. Bachman

A number of endocrine disorders are associated with varying degrees of glucose intolerance (Table 25-1). In most instances, the excess of a counterregulatory hormone (such as growth hormone, cortisol, epinephrine, or glucagon) is manifested by a distinct clinical syndrome associated with hyperglycemia or glucose intolerance. However, overt diabetes with symptomatic hyperglycemia, glycosuria, and ketosis secondary to an endocrinopathy is a relatively uncommon event, unless an underlying genetic diabetic diathesis is also present. Because of various beta-cell regulatory mechanisms,¹ endocrine factors potentially capable of disrupting glucose homeostasis in normal humans are offset primarily by appropriate increments and other adjustments of insulin secretion. The net outcome of the metabolic effects of an endocrinopathy in producing glucose intolerance is, therefore, usually dependent on its direct or indirect impact on one or more of the following: (1) insulin sensitivity (hepatic glucose production and/or peripheral glucose utilization); (2) insulin secretion (direct inhibition or compensatory hyperinsulinism); (3) unmasking of genetic diabetes; or (4) a familial polyendocrine disorder with a common underlying mechanism, such as a genetic mechanism (multiple endocrine neoplasia syndromes) and/or autoimmune factors. This chapter deals with the pathophysiology of glucose intolerance and related metabolic derangements associated with various types of endocrine disorders. The role of counterregulatory hormones in the pathogenesis and complications of genetic diabetes has been presented elsewhere.

DISORDERS OF GROWTH HORMONE SECRETION

A relation between the anterior pituitary gland and diabetes mellitus was first shown in the classic experiments by Houssay² and by Young³ using crude pituitary extracts. Subsequently, it was demonstrated that the administration of human growth hormone resulted in a marked deterioration of metabolic control in patients with diabetes.⁴

Secretion and Actions of Growth Hormone

Human growth hormone (GH) is secreted as a single strand of 191 amino acids sharing marked structural homology with placental lactogen and prolactin. A number of physiologic factors affect the secretion of GH in a healthy person.^{5,6} The stimuli for the release

of GH include sleep, muscular exercise, stress, hypoglycemia, and amino acids, whereas hyperglycemia is a potent suppressor of its release under normal circumstances.

GH has diverse metabolic effects on carbohydrate, protein, and lipid metabolism.^{5,7} Evidence indicates that GH contains multiple domains that determine its growth-promoting, diabetogenic, and insulin-like activities. For example, the carboxy-terminal sequences 44 to 191 and 182 to 191 were shown to induce hyperglycemia and insulin resistance in animal models,^{8,9} whereas the amino-terminal sequences 32 to 46 and 8 to 13 within the parent molecule have insulin-like actions.^{8,10} Employing a human forearm technique in a series of elegant experiments, Zierler and Rabinowitz showed the diabetogenic effects of acute increments of GH to occur via (1) an inhibition of glucose uptake by the skeletal muscle and the adipose tissue and (2) an augmentation of lipolysis.¹¹ Whether a significant lipolytic effect is seen during physiologic circumstances in normal individuals has not always been confirmed.^{5,12} With regard to in vivo glucose tolerance, supraphysiologic increments in circulating GH (30 to 40 ng/mL) were shown to result in an early but transient insulin-like effect consisting of a diminished glucose production and an enhanced peripheral glucose clearance; however, this was subsequently followed by a delayed insulin-antagonistic effect leading to hyperglycemia.¹³ In normal human subjects, several studies employing human pituitary growth hormone^{14,15} or recombinant DNA-derived human growth hormone administration,¹⁶ over a period of hours to days, reported the development of insulin resistance. In none of these studies was the degree of insulin resistance explained by changes in insulin receptor binding on monocytes, suggesting a postreceptor mechanism. Chronic administration of GH resulting in permanent diabetes in dogs is accompanied by eventual exhaustion of pancreatic beta cells.¹⁷

Up to 50% of GH is bound to growth hormone binding proteins (GHBP).^{18,19} The high-affinity GHBP has been found to correspond to the extracellular domain of the GH receptor. Although GHBP thus provides an indirect estimate of tissue GH responsiveness in general, there may be some exceptions to this relationship.¹⁹ Considerable evidence exists that many of the metabolic and growth-promoting effects of GH are mediated via the generation of a family of growth factors or somatomedins, produced by the liver in response to this hormone.^{5,7,20} The most prominent among these is insulin-like growth factor I (IGF-I). In contrast, there is also evidence that at least some of the effects of GH may be elicited by the physiologic concentrations of GH directly and

TABLE 25-1. Certain Endocrinopathies Associated with Glucose Intolerance

Disorders of growth hormone secretion
Growth hormone excess (acromegaly)
Growth hormone deficiency (sexual ateliotic dwarfism)
Hyperprolactinemic states
Glucocorticoid excess (Cushing's syndrome)
Catecholamine excess (pheochromocytoma)
Primary hyperaldosteronism
Hyperthyroidism
Disorders of calcium and/or phosphorus metabolism
Tumors of endocrine pancreas or gut
Glucagonoma
Somatostatinoma
Gastrinoma (Zollinger–Ellison syndrome)
Pancreatic cholera syndrome (Verner–Morrison syndrome)
Carcinoid syndrome
Multiple endocrine neoplasia (MEN)

independent of somatomedin generation.²¹ This view is further supported by the demonstration of the receptors for growth hormone in a variety of cell types including cultured human lymphocytes.

Acromegaly

The prevalence of glucose intolerance in acromegaly is about 50 to 60 percent, although symptomatic diabetes requiring treatment has been observed only in 10 to 30% of all patients.^{22–26} Even more frequent than glucose intolerance is a striking increase in serum insulin concentrations and decrease in insulin sensitivity to both endogenous and exogenous insulin that accompanies the GH excess in acromegaly. Defects in both hepatic and peripheral insulin action have been described, using insulin clamp studies.²⁷ GH levels correlate poorly with both the degree of glucose intolerance and the hyperinsulinemia; a better correlation of disease activity, including glucose intolerance, is found with the serum concentrations of IGF-I or IGF-binding protein 3 (IGFBP-3) levels.^{28,29} Muggeo and associates³⁰ showed a decreased concentration of insulin receptors on circulating monocytes and an inverse correlation of receptor concentration with the basal plasma insulin level in acromegaly. However, in most studies, there was no significant alteration in insulin receptor binding, probably explained by reciprocal changes in receptor affinity.²⁶ In some patients with acromegaly, the failure of the compensatory increase in receptor affinity may explain the development of hyperglycemia,³¹ although insulin dose–response studies in such patients suggest a postreceptor defect in insulin action.²⁷ The precise nature of the GH-induced postreceptor defect leading to inhibition of glucose transport across cell membrane remains unknown.

In contrast to the majority of patients with acromegaly who have hyperinsulinemia and impaired glucose tolerance, those with overt diabetes with or without ketosis clearly have a subnormal insulin reserve, suggesting an underlying genetic diabetic trait. Studies with somatostatin infusions in the human have provided evidence that growth hormone has significant effects on lipolysis or ketogenesis mainly in the presence of significant insulin deficiency.^{32,33}

Successful treatment of acromegaly is accompanied by striking improvement in glucose tolerance and restoration of normal serum insulin levels and normalization of insulin sensitivity in the

majority of patients with impaired glucose tolerance but infrequently so in those with overt, symptomatic diabetes.^{24–26,34} Lack of a complete remission in many patients may be due to incomplete cure of acromegaly, defined as suppression of GH to less than 2.5 ng/mL or to less than 1 ng/mL after oral glucose, using newer, ultra-sensitive assays.³⁵ The increase in mortality rate in acromegaly may persist unless GH levels are suppressed to near-normal range.^{36,37} Moreover, glucose intolerance and hypertension are independent determinants of acromegalic cardiomyopathy.³⁸

The long-acting somatostatin analog, octreotide, has been shown to be a useful adjunct in the treatment of acromegaly. In large, multicenter trials of 58 and 103 patients, lasting up to 30 months,^{39,40} most of whom had been previously treated with surgery or radiotherapy, treatment with octreotide for more than 6 months resulted in substantial improvement in about 65% of patients. However, biochemical cure, defined by GH less than 5 ng/mL and normal IGF-I occurred in about 50 percent of patients, and only 20 to 40 percent of patients fulfilled the more stringent criterion of GH suppression to less than 2ng/mL in both of these large series of patients.^{39,40}

Regarding the effects of octreotide therapy on glucose tolerance, the results from various reports indicate a mixed outcome, depending on the baseline metabolic status.²⁶ On the one hand, in patients with overt diabetes or IGT, significant improvement in glucose tolerance or normalization of diabetes may result after several weeks of treatment. Impressive decreases in insulin requirements among the diabetic subjects within the largest, randomized, multicenter trial were observed.⁴⁰ Normalization of GH and IGF-I were associated with improvements in insulin sensitivity and greater suppression of hepatic glucose output (HGO) as determined by the euglycemic-hyperinsulinemic clamp technique, whereas peripheral glucose disposal was not affected.⁴¹ On the other hand, in patients with normal or minimally impaired glucose tolerance, treatment with octreotide resulted in either slight improvement, no change, or even a worsening of glucose tolerance, despite improvements in GH and IGF-I levels.^{26,39,42} Thus, an adverse outcome in glucose homeostasis may be seen in some nondiabetic acromegalic patients following treatment with octreotide, depending on baseline characteristics such as β -cell reserve and degree of insulin resistance. Finally, long-term octreotide therapy may result in other side effects, the most important of which is the 40 to 50 percent incidence of cholelithiasis and/or biliary sludge.⁴⁰

Recently, results with longer-acting somatostatin analogs (Octreotide LAR and Lanreotide) have shown comparable decreases in GH and IGF-I levels but the long-term effects on glucose homeostasis with these agents are awaited. Similarly, impressive short-term clinical outcome data with a growth hormone receptor antagonist, Pegvisomant, in a large series of patients with acromegaly were reported recently.⁴³ The effects of this novel approach on glucose intolerance will also be of interest.

Diabetes Associated with Growth Hormone Deficiency

The presence of diabetes in the setting of GH-deficient dwarfs presents an interesting paradox. However, it has been known for a number of years that exogenous administration of GH to both normal and hypopituitary subjects augments the insulin response to a variety of secretagogues before a significant change in blood glucose occurs.⁴⁴ Martin and Gagliardino⁴⁵ showed a β -cytotropic effect of GH on isolated pancreatic islets of rat *in vitro*. Similarly,

some workers have shown direct effects of GH on islet β -cell replication in neonatal rat islet monolayer cultures.⁴⁶

The majority of adult sexual ateliotic dwarfs with monotropic GH deficiency studied by Merimee and coworkers, showed evidence of a mild to moderately severe glucose intolerance and insulin deficiency.⁴⁷ In addition, GH deficiency may promote visceral obesity, and in turn reduce insulin action as well (see Chapter xxxxxx). Interestingly, after 10 years of follow-up, there was no evidence of diabetic microangiopathy in these dwarfs, despite worsening of glucose intolerance.⁴⁸ On the one hand, these observations support the concept of a permissive role of GH in the pathogenesis of diabetic vascular disease. On the other hand, the incidence and severity of microangiopathy in patients with acromegaly with a striking increase of ambient GH concentrations does not appear to be increased and may indeed be significantly lower than in patients with genetic diabetes. Further studies on groups of patients well matched for the degree and duration of hyperglycemia are required to settle this question.

A number of long-term follow-up studies in adult patients with hypopituitarism have suggested an increased cardiovascular mortality even after replacement of other hormones.⁴⁹ This has been partly ascribed to an atherogenic lipid profile, visceral adiposity, and insulin resistance in such patients. Administration of GH in such patients may restore, although not normalize the cardiovascular risk profile.⁵⁰ Short-term studies with GH therapy over 12 to 30 months have also reported adverse effects on glucose tolerance and insulin sensitivity in hypopituitary adults.^{51,52} Retinal changes, mimicking diabetic retinopathy, were reported in two non-diabetic patients after 14 to 17 months of treatment with GH.⁵³ However, only 12 cases of overt diabetes were reported among 8136 GH-treated children.⁵⁴

GH is currently being proposed by some as therapeutic agent for several indications (e.g., preservation of lean body mass during aging, HIV-related disorders, prolonged illness, osteoporosis, enhancing tissue repair following surgery or trauma, and stimulation of muscle mass in athletes). Besides its potential for diabetogenic effects, other long-term risks of GH therapy need to be studied before specific recommendations can be made.⁵⁵

Hyperprolactinemia

GH and prolactin share considerable structural homology. A role of prolactin in the pathogenesis of a human diabetogenic syndrome was suggested by the studies of Landgraf and colleagues.⁵⁶ These investigators studied the blood glucose and insulin levels during oral glucose tolerance tests in 26 patients with prolactin-secreting pituitary tumors. The basal glucose and insulin levels were similar to control subjects despite chronic, endogenous hyperprolactinemia; however, glucose tolerance was significantly impaired and was accompanied by a relative peripheral insulin insensitivity as reflected by the associated hyperinsulinemia. Both glucose intolerance and hyperinsulinism improved after suppression of prolactin release following treatment with bromocriptine. In a study of nine patients with amenorrhea-galactorrhea syndrome and hyperprolactinemia, mildly abnormal glucose tolerance and elevated insulin levels were found.⁵⁷ On the other hand, the 24-hour plasma prolactin pattern in a group of relatively stable, insulin-dependent (juvenile) diabetics was found to be identical to that in normal controls,⁵⁸ suggesting a normal regulation of prolactin secretion in such diabetics. In contrast, elevated plasma concentrations of prolactin have been reported in diabetics in ketoacidosis,⁵⁹ a finding not confirmed by oth-

ers,⁶⁰ even after stimulation with TRH. Further studies are clearly required in the delineation of metabolic aberrations, if any, associated with the syndrome of prolactin excess.

Cushing's Syndrome

It has been known for a long time that glucocorticoids antagonize the actions of insulin. The spectrum of insulin insensitivity in patients with Cushing's syndrome and the insulin hypersensitivity in Addison's disease is clinically well recognized. Cahill⁶¹ has reviewed extensive evidence for the diverse metabolic actions of glucocorticoids on liver, adipose tissue, and muscle.

In the liver, glucocorticoids appear to accelerate the biochemical actions at every rate-limiting step in the sequence of events leading to gluconeogenesis.^{61,62} Some of these crucial loci are (1) hepatic uptake of amino acids, (2) activation of pyruvate carboxylase in generating pyruvate from amino acid precursors, and (3) activation of phosphoenolpyruvate carboxykinase, the unidirectional rate-limiting enzyme in the initiation of the cascade of gluconeogenesis from pyruvate. Glucocorticoids, paradoxically, stimulate glycogen deposition and in this respect resemble the action of insulin; in fact, some evidence suggests that the glycogen-synthesizing effect of glucocorticoids may be mediated via insulin, rather than a direct steroid effect. At the level of adipose tissue and muscle, the main effect of glucocorticoids involves an antagonism of insulin-induced glucose transport by multiple mechanisms including a decrease in insulin-receptor affinity, as well as a defect in insulin-receptor signaling.⁶²⁻⁶⁴ In addition, glucocorticoids appear to exert a permissive effect on lipolysis by promoting the activation of cAMP-dependent, hormone-sensitive lipase in the adipose tissue of several species. However, the net clinical effect of glucocorticoid excess in humans is generally not fat mobilization but a relocation of fat depots, resulting in typical truncal obesity. Recent studies have suggested differential effects of glucocorticoids on adipose tissue of omental versus subcutaneous regions.⁶⁵ In these studies, both the glucocorticoid receptor binding and the LPL activity were two- to fourfold higher in the omental adipose tissue. Several *in vitro* studies have shown an augmentation of proteolysis in skeletal muscle and perhaps a decreased incorporation of amino acids in the muscle protein. A shift in muscle fiber composition from type I to type IIb has been described in patients with Cushing's syndrome.⁶⁶ Finally, glucocorticoids may have a direct effect on insulin release by inhibition of Ca^{2+} -induced exocytosis.⁶⁷

In normal humans, short-term increments of plasma cortisol within the ranges up to those seen in moderate stress situations result in a mild increase of glucose levels secondary to both hepatic and extrahepatic effects, as well as in a significant increase in blood ketone and branched-chain amino acid levels.^{62,63} These changes were accompanied by no significant alterations in insulin receptors, supporting a role for postreceptor mechanisms underlying the decrease in insulin sensitivity. However, the hyperglycemic effects of chronic administration of glucocorticoids in normal subjects with an intact islet reserve are partially compensated for by secondary changes in insulin release, so that the net effects observed on glucose levels may be minimal or moderate. The spectrum of glucose intolerance in a patient with Cushing's syndrome is therefore largely dependent upon the endogenous β -cell reserve, similar to the situation in acromegaly. Glucose intolerance in Cushing's syndrome has been reported to be present in 75 to 80 percent of patients, although overt diabetes occurs in about 10 to 15 percent of all patients.⁶⁸ Nearly all patients manifest basal and stimulated

hyperinsulinemia and insulin insensitivity. The diabetogenic effect in glucocorticoid-excess states also involves a stimulation of glucagon secretion. Glucocorticoid administration in normal volunteers over 3 to 4 days^{69,70} was shown to induce an augmented α -cell responsiveness both in the basal state and following protein ingestion or amino acid infusion. This effect may be mediated indirectly via hyperaminoacidemia brought about by augmented proteolysis and, perhaps by other factors, such as decreased islet glucose utilization, or a direct effect of the steroid upon the α cell.

Pheochromocytoma

Catecholamines, acting via adrenergic receptors, produce their effects on islet secretion and in several loci of intermediary metabolism.⁷¹ The classical effect of epinephrine (E) in enhancing hepatic glucose output via glycogenolysis results primarily via β_2 adrenergic stimulation of adenylcyclase and cAMP release. In addition, E stimulates glycogenolysis also by an α -adrenergic, Ca^{++} -dependent but cAMP-independent mechanism.⁷² On the other hand, stimulation of adipose tissue lipolysis and muscle glycogenolysis is mediated by β -adrenergic mechanisms.⁷¹ In vitro studies performed by Garber and associates⁷³ have revealed a significant inhibition of the release of gluconeogenic amino acids (alanine and glutamine) in response to β -adrenergic agonists. Moreover, recent studies with E infusions in normal humans achieving physiologic concentrations in the range of 350 to 400 pg/mL revealed a significant decline in circulating amino acids (particularly branched-chain), which was preventable by the β -adrenergic antagonist propranolol. The significance of these effects of catecholamines on muscle protein balance requires further elucidation.

Studies in normal subjects receiving physiologic infusions of E have shown only a transient stimulation of hepatic glucose output and a sustained inhibition of peripheral glucose uptake.⁷⁴ The latter effect is mediated via a β -adrenergic stimulation in muscle. Norepinephrine was found to have much less pronounced direct hyperglycemic effects, and the effects of epinephrine were not mediated via glucagon hypersecretion.⁷⁴

A number of studies have been performed to study the adrenergic regulation of islet hormone secretion. Robertson and co-workers⁷⁵ provided evidence for inhibition of basal insulin secretion by α -adrenergic stimulation or by β -adrenergic blockade. In addition, they postulated that an excessive endogenous α -adrenergic activity may contribute to the defective glucose-stimulated insulin secretion in type 2 diabetes. However, the role of catecholamines in the physiologic regulation of insulin secretion and in the pathogenesis of diabetes remains controversial. Recently, a 29-amino-acid

polypeptide, galanin, was proposed as an important mediator of sympathetic neural activation in the endocrine pancreas.⁷⁶ However, its effects may be restricted to nonprimates. Regarding the pancreatic α cell, both α - and β -adrenergic stimulation have been shown to augment glucagon secretion, although the relative importance of α - and β -sympathetic versus the parasympathetic tone in maintaining basal glucagon release remains uncertain.^{71,77}

In patients with pheochromocytoma, fasting glucose at or higher than 126 mg/dL was reported in about 30% of patients⁷⁸ from multiple mechanisms, including (1) an inhibition of insulin secretion, (2) stimulation of hepatic and muscle glycogenolysis and hepatic glucose output, and (3) enhanced lipolysis. In animals epinephrine has been shown to decrease the transcription of the glucose transporter 4 (GLUT-4) gene.⁷⁹ Administration of α -adrenergic blocking agents, such as phenoxybenzamine, characteristically improves β -cell secretory response and glucose tolerance.⁷¹ Glucagon levels were found to be within the normal range in the basal state, and suppressed in response to arginine⁸⁰ or hypoglycemia⁸¹ in patients with confirmed pheochromocytoma. As a rule, surgical removal of the tumor restores or improves glucose tolerance^{78,80} within several weeks postoperatively. However, others have reported a normal increase with arginine.^{71,82}

Table 25-2 summarizes the major sites of action of various counterregulatory hormones at the levels of target organs and the principal mechanisms of diabetogenic effects. In addition, the net outcome of these effects is dependent upon the direct or indirect influences on the secretion or actions of insulin (Table 25-3), as discussed previously.

Primary Hyperaldosteronism

The triad of hypertension, hypokalemia, and glucose intolerance was first described by Conn.⁸³ Contrary to previous expectations, it has been estimated that this syndrome accounts for certainly no more than 1–2% of the hypertensive population.

Glucose intolerance was earlier reported to be present in about 50% of the patients with this syndrome,⁸³ but a more accurate incidence would be considerably lower in view of a relatively mild abnormality in most patients even with the current criteria for the diagnosis of diabetes. The metabolic abnormality linked to glucose intolerance is generally thought to be secondary to potassium depletion, which may be responsible for the reported blunted insulin secretion^{83,84} and perhaps accelerated glycogenolysis. Sagild and associates⁸⁵ were able to induce glucose intolerance in normal men commensurate with the induction of a potassium depletion to the extent of 200–500 mEq during a 5-day period, while the insulin

§ Indirectly via potassium depletion.

¶ A pharmacologic effect.

Probably via an effect on phosphorus metabolism as a major mechanism.

sensitivity remained unchanged. However, potassium depletion may not be the only explanation for the glucose intolerance in primary aldosteronism.⁸⁶

THYROID DISORDERS

Hyperthyroidism

Mild to moderately severe degrees of glucose intolerance have been documented in 30–50% of patients with hyperthyroidism.^{87,88} Several effects of thyroid hormone excess have been related with aberrations of intermediary metabolism of carbohydrate, lipid, and protein.⁸⁸ Induction of hyperthyroidism in subjects with and without diabetes has been found to augment hepatic glucose production and perhaps renal gluconeogenesis. A rapid gastric emptying rate itself may contribute to postprandial hyperglycemia in some thyrotoxic patients. The data on insulin secretion and insulin sensitivity in hyperthyroid patients are controversial.^{68,89,90} Several studies have shown subnormal insulin responsiveness to oral glucose, IV glucagon, and IV arginine; however, others have reported normal or increased β -cell responsiveness, but a decreased C-peptide to insulin molar ratio. The significance of the latter finding is uncertain in view of reports of a significantly increased metabolic clearance rate of insulin in such patients.⁹¹ The elevated free fatty acid levels seen in hyperthyroid patients⁸⁸ might also contribute to glucose intolerance. Beylot and associates have found evidence for augmented ketogenesis, probably mediated in part by a β -adrenergic mechanism.⁹² Along with the evidence from isolated liver perfusion experiments in which thyroxine was shown to enhance gluconeogenesis from alanine,⁸⁸ these observations would support the clinical observation of worsening glycemic control and recurrent ketoacidosis in patients with preexisting diabetes mellitus who develop thyrotoxicosis.⁹³ Glucose intolerance persisted in 32% (7 of 22) of patients studied by Maxon and coworkers⁸⁷ after 12 years of follow-up after treatment. Because both Graves' disease and type I diabetes share similar autoimmune mechanisms, an increased coexistence of these two disorders may be at least partly explained on this basis.⁹⁴

DISORDERS OF CALCIUM AND/OR PHOSPHORUS METABOLISM

Disorders of calcium and phosphorus metabolism produce significant alterations in insulin secretion and/or insulin sensitivity though the extent of these alterations and their precise mechanism remain uncertain. In primary hyperparathyroidism, elevated serum calcium levels are associated with hyperinsulinism.^{95,96} and the insulin hypersecretion pattern has been found to correlate with serum calcium level.⁹⁵ The presence of glucose intolerance in 40% of such patients⁹⁷ suggests a state of tissue insensitive to insulin due to the raised intracellular free calcium in primary hyperparathyroidism. However, studies in dogs⁹⁸ and humans also point to an important role of hypophosphatemia in inhibiting glucose disposal and an impairment of tissue sensitivity to insulin. This could be, therefore, an important contributory mechanism underlying the insulin resistance of primary hyperparathyroidism. That parathyroid hormone has little direct effect on glucose disposal or insulin secretion is suggested by the studies in dogs with diet-induced secondary hyperparathyroidism⁹⁴ and in patients with renal insufficiency who showed no significant effect of parathyroidectomy on any of these parameters.¹⁰⁰ Patients with idiopathic hypoparathyroidism or pseudohypoparathyroidism may have impaired insulin secretion associated with hypocalcemia.⁹⁵

The α -cell responses to arginine or to a protein meal and glucose were studied in a series of patients with primary hyperparathyroidism before and after removal of parathyroid adenoma and were found to be intact.⁹⁶ In several, but not all, patients with preexisting diabetes mellitus who underwent parathyroidectomy for primary hyperparathyroidism, evidence for significant improvement in glucose tolerance and for increased sensitivity to exogenous or endogenous insulin was reported.^{97,101} These observations further indicate potential consequences of the disorders of calcium and/or phosphorus metabolism on glucose tolerance, insulin secretion, and insulin sensitivity.

TUMORS OF THE ENDOCRINE PANCREAS OR GUT

Non- β -cell tumors of the endocrine pancreas associated with glucose intolerance include particularly those characterized by glucagon and somatostatin hypersecretion. Subtle abnormalities of carbohydrate metabolism have also been encountered in some patients with gastrinoma, vasoactive inhibitory polypeptide tumor (VIP-oma), and carcinoid syndrome. Additionally, diabetes or glucose intolerance may be a component of the multiple endocrine neoplasia (MEN) syndromes.

GLUCAGONOMA

Clinical Features

Since the first well-described patient with a glucagon-secreting tumor in 1966 and a clear definition of the glucagonoma syndrome in 1974, there are now more than 130 definite, well-documented cases in the literature.^{102–104} The salient clinical features are summarized in Table 25-4. The syndrome is most prevalent in postmenopausal women, and the tumor is found to be malignant in the majority of patients, usually originating in the body or tail of the

TABLE 25-4. Salient Features of the Glucagonoma Syndrome

Incidence: women > men
Clinical features:
Glucose intolerance
Skin rash: necrolytic migratory erythema
Anemia: normochromic, normocytic
Atrophic glossitis or stomatitis
Thromboembolic disease
Weight loss
Biochemical features:
Hyperglucagonemia, usually > 1000 pg/mL
Hypoaminoacidemia
Associated hormonal secretion:
Insulin, ACTH, parathyroid hormone, or PTH-like substance, pancreatic polypeptide, gastrin, serotonin, vasoactive intestinal polypeptide, melanocyte-stimulating hormone
Pathology: malignant >> benign

pancreas. Glucose intolerance, a characteristic skin rash, and anemia, the clinical triad of this syndrome, are present in 70–80% of patients. The less common features include unexplained severe weight loss, atrophic glossitis or stomatitis, thromboembolic phenomena, diarrhea, and psychiatric disturbances. Rarely, glucagonoma has been described as part of the MEN I syndrome. More commonly, in about 20–30% of patients, the pancreatic tumor itself was documented to secrete one or more of several other polypeptide hormones, including insulin, ACTH, PTH, or PTH-like substances, pancreatic polypeptide (PP), gastrin, VIP, MSH, and, rarely, serotonin.

The necrolytic migratory erythema¹⁰⁵ is characterized as a disabling, chronic, intermittent, bullous dermatopathy presenting as single or confluent areas of desquamating, maculopapular, exudative lesions. The areas most commonly involved include groin, perineum, and buttocks, but almost any other area may be involved. Healing of several lesions is followed by hyperpigmentation; recurrence in the areas of trauma or friction is frequent.

Biochemical Features

The circulating glucagon levels in most patients are very high, ranging between 1000 and 7000 pg/mL, two orders of magnitude higher than those seen in other states of marked glucagon excess such as uncontrolled diabetes, stress, trauma, hepatic or renal insufficiency, and hypercortisolism. However, in a rare syndrome of familial hyperglucagonemia, probably inherited as an autosomal dominant trait,^{106,107} striking hyperglucagonemia may sometimes be observed at levels indistinguishable from those usually seen in glucagonoma syndrome. Interestingly, in one study¹⁰⁶ elevated basal glucagon levels were observed in several relatives of a patient with glucagonoma. Most patients with glucagonoma secrete variable proportions of both 3500- and 9000-d (proglucagon) fractions, whereas the major fraction of glucagon in patients with familial hyperglucagonemia elutes in the 9000- and 30,000-d range.¹⁰⁷

Hypoproteinemia and, more consistently, marked hypoaminoacidemia have been frequently reported in patients with glucagonoma. In some patients, concentrations of several gluconeogenic amino acids including threonine, proline, arginine, and alanine were decreased to 10% of normal but returned to normal range after successful resection of the tumor.¹⁰⁸ The markedly decreased amino acid levels probably reflect enhanced hepatic ex-

traction. Regardless of the exact mechanism of hypoaminoacidemia, it has been suggested that the amino acid deficiency may be causally related to the dermatopathy of the syndrome, because parenteral supplementation with amino acids may result in marked amelioration in skin rash, commensurate with the restoration of amino acid levels.¹⁰⁹

GLUCOSE INTOLERANCE

Despite striking elevations of circulating glucagon levels, the glucose intolerance in this syndrome is usually only mild to moderately severe, reflecting the key role of pancreatic insulin reserve in determining the diabetic status. In some patients, hyperglycemia may worsen simply because of the infiltration of the normal pancreatic tissue by the tumor mass, spuriously suggesting a correlation between the rising glucagon levels and the glucose intolerance.¹⁰² In patients in whom the tumor mass is not overwhelming, the peripheral insulin levels have been found to be normal or appropriately increased, in keeping with hyperglycemia. Development of ketoacidosis has been a rare occurrence¹¹⁰; when demonstrable, it probably reflects an insulin-deficient state due to an underlying true genetic diabetic trait.

Therapy

The skin lesions of the glucagonoma syndrome have been treated with various modalities including topical corticosteroids, antifungal agents, oral tetracyclines, or zinc, with variable success rates. Rapid improvement of skin lesions was noted in two patients following prolonged infusions of somatostatin.¹¹¹ and in some patients after parental amino acid infusions or total parenteral nutrition.¹⁰⁹ The occasional spontaneous remissions of the dermatopathy in the natural history present some difficulty in assessing the response to any of the therapeutic maneuvers.

The definitive treatment of glucagonoma syndrome consists of total excision of tumor, although this is feasible in only a minority of patients. When complete, a dramatic remission of the dermatopathy and all the other manifestations of the syndrome has been reported. For the nonresectable tumors, most of which are accompanied by hepatic metastases, streptozocin has been the most frequently employed chemotherapy. The results have not been uniformly good. A combination of streptozocin and doxorubicin was found to be significantly more efficacious than streptozocin alone or streptozocin plus fluorouracil for the treatment of all forms of islet-cell carcinoma,¹¹² although enough experience with this regimen in glucagonoma is yet to be established. Encouraging results have also been obtained with dimethyltriazenoimidazole carboxamide (DTIC) in several patients with glucagonoma. In patients with hepatic-dominant metastases, hepatic artery occlusion by surgery or embolization, followed by chemotherapy, may be more effective than chemotherapy alone.¹¹³ The effectiveness of a long-acting somatostatin analogue, octreotide, in suppressing glucagon release from inoperable tumors and associated clinical benefits were demonstrated in some patients.¹¹⁴

SOMATOSTATINOMA

The association of diabetes in patients with somatostatin-containing pancreatic tumors is part of a fascinating, although rare,

clinical syndrome. The somatostatinoma syndrome also provides an opportunity to study the diverse pathophysiologic effects of chronic endogenous somatostatin excess resulting from such tumors.

Since the initial reports in 1977,^{115,116} more than 20 patients with somatostatinoma-secreting pancreatic tumors have been well documented.¹¹⁷ Occasionally, variable amounts of somatostatin may be an incidental finding in a variety of neuroendocrine tumors, reflecting the multihormonal heterogeneity of such tumors. In addition, there are more than 50 recorded cases of duodenal carcinoids containing somatostatin, frequently in association with neurofibromatosis type I.^{117,118} Interestingly, almost all of the patients with pancreatic somatostatinoma had diabetes, whereas those with extrapancreatic somatostatinoma lacked diabetes, suggesting that a paracrine action of somatostatin in inhibiting islet hormone secretion, particularly insulin, might be the predominant diabetogenic mechanism in these patients. However, the presence of a number of other clinical manifestations, such as gallbladder disease (most common), diarrhea (with or without steatorrhea), hypo- or achlorhydria, weight loss, and anemia, in many of the patients would suggest that the markedly raised circulating somatostatin concentrations do produce expected multiple biologic effects in patients with this syndrome.¹¹⁷ Table 25-5 presents a clinicopathologic classification of somatostatin-secreting tumors.

The diabetes in the patients with pancreatic somatostatinoma has generally been of mild to moderate severity, although in a few patients, significant ketosis and even ketoacidosis were present.^{119,120} The immunoreactive insulin, glucagon, pancreatic polypeptide, and growth hormone levels were often blunted when measured. In all except a few of the patients, there was evidence of significant metastases by the time of diagnosis, culminating in fatal outcome or necessitating chemotherapy. In only one patient, successful excision of the pancreatic tumor resulted in complete disappearance of diabetes,¹²¹ and she remains asymptomatic after 25 years. A follow-up arginine stimulation test in this patient revealed restoration of insulin, glucagon, and growth hormone responses, suggesting a causal relation between the patient's tumor and the induced metabolic aberrations. Another patient was free of symptoms, including remission of diabetes, 2 years after successful resection.¹²²

The characterization of circulating and tissue somatostatin-like immunoreactivity (SLI) carried out in some of the patients revealed predominantly large-molecular-weight SLI, suggesting precursor

secretory proteins.^{117,123,124} In one patient, there was evidence of greater release of precursor proteins from the metastatic than from the primary tumor tissue,¹²³ and in one patient the tumor cell could be grown in monolayer cultures and released somatostatin into the culture medium.¹¹⁷ The ultrastructural and immunohistochemical studies in most of the reported patients revealed the presence of typical D cells as the predominant cell form in these tumors. However, multiple hormone production due to mixed cellularity of malignant islet cell tumors is not an uncommon occurrence. In some patients, the clinical symptoms from the secretion of a second or even third major hormone may result months to years following the initial diagnosis.¹²⁵ This may also explain the seemingly unrelated symptoms in certain patients thought to have "somatostatinoma" on a morphologic basis in whom the clinical presentation may be due to a different major hormonal secretion such as insulin.^{126,127} In several other patients, there was evidence of overproduction of calcitonin from the pancreatic tumor as seen by the immunohistochemical studies as well as by the markedly elevated plasma calcitonin levels in the absence of evidence for coexisting medullary carcinoma of thyroid. Of additional interest in this regard are the findings¹¹⁷ of ectopic somatostatin-secreting cells in some patients with medullary carcinoma of thyroid, and in oat-cell tumors of lung. These findings support the theory of a common derivation of these three types of tumors among those from the amine precursor uptake decarboxylation (APUD) cellular origin.

The experience with chemotherapy in patients with metastatic somatostatinoma is limited. Several patients underwent treatment with streptozocin, 5-fluorouracil, or both, but long-term follow-up was generally disappointing. Newer regimens including doxorubicin in combination with streptozocin may hold promise, as shown for other forms of islet cell malignancies.¹¹³

GLUCOSE INTOLERANCE IN PATIENTS WITH OTHER TYPES OF ENDOCRINE TUMORS

Gastrinoma (Zollinger–Ellison) Syndrome

Glucose intolerance has occasionally been reported in patients with the Zollinger–Ellison (ZE) syndrome, chiefly characterized by (1) hypersecretion of gastric acid, (2) recurrent peptic ulcers, and

TABLE 25-5. Classification of Somatostatin-Producing Tumors

Type	Common Site(s) of Origin	Mode of Clinical Presentation	Associated Diseases or Syndromes	Cases Reported (n)
A	Pancreas	Somatostatinoma syndrome (diabetes, cholelithiasis, diarrhea, anemia, hypochlorhydria)	—	20–25
B	Duodenal, ampullary, or perampullary mucosa	Abdominal pain, GI bleeding, biliary obstruction, incidental finding	Von Recklinghausen's neurofibromatosis, MEN type IIb syndrome, pheochromocytomas, paragangliomas, carcinoids elsewhere, carcinoma of pancreas	50–55
C	Pancreas, GI tract, paraganglia, thyroid, lung, etc.	Very variable: Cushing's syndrome, ZE syndrome, carcinoid syndrome, hypoglycemia	Celiac disease (one case)	15–20

Modified with permission from Ganda OP, Dayal Y. Somatostatin-producing tumors. In: Dayal Y, ed. *Endocrine Pathology of the Gut and Pancreas*. Boca Raton: CRC Press; 1991:241–277.

(3) a gastrin-producing tumor. The tumors of this type originate from the pancreas or, not infrequently, from the duodenum or from both sites. The cell of origin in pancreas is probably from a subset of D cells, and some evidence indicates that both gastrin and somatostatin may be secreted by the same D cells,¹²⁸ although others have been unable to detect gastrin in normal islets.¹²⁹

The effect of hypergastrinemia associated with the ZE syndrome on pancreatic islet hormone secretion has not been studied in detail. It is, therefore, not clear if the glucose intolerance seen in some patients with ZE syndrome is causally related to gastrin overproduction. Moreover, in about 20–60% of patients with ZE syndrome,¹³⁰ other endocrine tumors coexist as part of the multiple endocrine neoplasia (MEN) syndrome, one or more of which may have diabetogenic effects (as is discussed later).

Pancreatic Cholera Syndrome

In 1958, Verner and Morrison described a syndrome characterized by severe watery, cholera-like diarrhea, hypokalemia, and achlorhydria (WDHA syndrome or Verner–Morrison syndrome) in association with an islet cell tumor and subsequently reviewed 55 patients with this entity.¹³¹ Other clinical features of the syndrome include episodic flushing of skin, hypercalcemia, and hyperglycemia, the latter being found in about one-third of patients.¹³² The possibility exists that glucose intolerance, at least in some patients, is related to the severe hypokalemia, an integral component of this syndrome.

Many, but not all, patients with this syndrome have elevated concentrations of vasoactive intestinal peptide (VIP). Several investigators have reported patients with classical pancreatic cholera syndrome with normal concentrations of VIP (pseudo-Verner–Morrison syndrome). In this latter situation, the nature of the causative agent(s) mediating the syndrome remains uncertain although a number of likely candidates have been proposed, including calcitonin, pancreatic polypeptide, prostaglandins, substance P, neurotensin, and peptide histidine-methionine (PHM), a peptide that shares a common precursor with VIP.¹³³

Carcinoid Syndrome

Glucose intolerance is occasionally seen in patients with carcinoid syndrome, an endocrine disorder with protean manifestations.¹³⁴ Feldman and coworkers¹³⁵ showed an inhibitory effect of serotonin on insulin secretion in several experimental animals, and reported a potentiation of insulin secretion *in vitro* by a serotonin antagonist, methysergide maleate. These observations supported the concept of biogenic amines modulating insulin secretion. Subsequently, the same investigators studied a series of patients with carcinoid syndrome.¹³⁶ Glucose intolerance (by intravenous glucose tolerance testing) was documented in 8 of 10 patients with metastatic carcinoid tumors, presenting with the carcinoid syndrome and elevated serum serotonin levels. In contrast, all seven patients with metastatic carcinoid tumors but without the carcinoid syndrome (normal serotonin levels) had a normal IV glucose tolerance. Administration of a serotonin antagonist, cyproheptadine, or *p*-chlorophenylalanine, which blocks serotonin synthesis, resulted in enhanced insulin secretion and, in the latter instance, some improvement in glucose disposal rates. None of the patients in this series had evidence of overt diabetes, although oral glucose tolerance tests were not performed. Thus, subtle aberrations of carbohydrate metabolism may exist in patients with carcinoid syndrome.

Multiple Endocrine Neoplasia

As discussed previously, it is important to recognize that the clinical picture and differential diagnosis of several endocrine tumor syndromes are sometimes complicated by the fact that multiple hormones might be produced by one “specific” type of tumor, as reported in some patients with glucagonoma or somatostatinoma. Perhaps more commonly, the pathologic hypersecretion of several hormones occurs in an individual patient simply on the basis of multiple endocrine neoplasia. Three such constellations of multiple endocrine neoplasia (MEN) syndromes have been described, each as a familial syndrome with autosomal dominant inheritance.¹³⁷ MEN type I (Wermer’s syndrome) most frequently consists of the involvement of the pituitary gland, pancreatic islets, and parathyroids, sometimes in association with tumors of the adrenal cortex or thyroid, or with carcinoid tumors, lipomas, or thymomas. Of the pancreatic tumors present in 60–80% of patients with MEN I, gastrinomas and insulinomas are the ones most frequently observed. MEN type IIA (Sipple’s syndrome) is characterized by pheochromocytoma, hyperparathyroidism, and medullary carcinoma of the thyroid. A variant of the syndrome, MEN type IIB, consists of pheochromocytoma, medullary carcinoma of the thyroid, mucosal neuromas, hyperplastic corneal nerves, and marfanoid habitus. However, overlap between these MEN categories does occur, so that it is not certain if these are distinct genetic syndromes and discrete classification types.¹³⁷ Recently, a MEN type II gene was identified on chromosome 10 and a MEN I gene on chromosome 11q13.^{138,139} Mutations in the RET protooncogene have been identified in MEN IIA and IIB syndromes, but the role of this gene product in the pathogenesis of diabetes remains uncertain. The RET protooncogene is a transmembrane tyrosine kinase receptor whose overexpression in transgenic mice results in medullary thyroid cancer but not glucose intolerance syndromes.¹⁴⁰

POEMS Syndrome

POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes), also known as Krow–Fukasi syndrome, is a rare form of plasma cell disorder associated with osteosclerotic myeloma. About 100 cases have been reported.¹⁴¹ The endocrine components of this syndrome include diabetes, hypogonadism with or without hyperprolactinemia, hypothyroidism, and adrenal insufficiency. Polyneuropathy is almost always a clinically manifested feature along with IgG or IgA type M protein and lambda-type light chain. Glucose intolerance, sometimes requiring insulin, has been reported in 30–50% of cases.¹⁴²

Nutritional Management of the Person with Diabetes

Abhimanyu Garg

Joyce P. Barnett

INTRODUCTION

Nutritional guidelines for patients with diabetes mellitus have been changing over the past century based on new scientific knowledge. The American Diabetes Association (ADA) Task Force on Nutritional Guidelines made major revisions compared to the previous guidelines of 1994.¹ Most recently, evidence-based nutritional guidelines have been proposed.² These guidelines address the importance of optimizing plasma glucose and lipid levels, as well as issues related to growth and development, pregnancy and lactation, aging, prevention of short- and long-term complications, and overall optimal health through good nutrition. Nutritional management, or medical nutrition therapy, is an integral component of overall management of diabetes, but is extremely challenging to implement successfully. The goal of nutrition therapy “is to assist individuals with diabetes in making changes in nutrition and exercise habits leading to improved metabolic control.”^{1,3} Specific goals of therapy are outlined in Table 26-1. The purpose of this chapter is to review the scientific rationale for nutritional management and provide practical insight on how to implement nutrition therapy to optimize diabetes management.

HISTORICAL PERSPECTIVE

The earliest known recommendations for treatment of diabetes included references to what we now consider to be carbohydrate-containing foods. Even then the debate was whether a high-carbohydrate or a low-carbohydrate diet was most beneficial for someone with diabetes. In the 1600s and 1700s this controversy continued. In the 1800s attention was given for the first time to specific amounts of foods, when it was recognized that amino acids could yield glucose in the body via gluconeogenesis.⁴ Prior to the discovery of insulin in 1921, the primary treatment for diabetes mellitus was an extremely low-energy, low-carbohydrate diet (Table 26-2).³ Although the ADA guidelines somewhat liberalized carbohydrate intake in the 1950s, the focus continued to be primarily on restriction of carbohydrate until the 1970s. The longer survival of people with diabetes that resulted from improved treatment then shifted attention to long-term complications. The increased risk for cardiovascular disease in individuals with diabetes shifted the focus toward restriction of dietary fats, particularly saturated fats, and cholesterol, which received increasing emphasis through

the 1980s and into the 1990s. This led to further liberalization of carbohydrate intake. The recommendations issued in 1994 and 2002 are based to a greater degree on scientific evidence and less on clinical practice than previously issued recommendations. Recent studies have emphasized the importance of rigorous glycemic control in the prevention of long-term diabetic complications, and therefore greater emphasis on nutritional management should help achieve normoglycemia.^{5,6}

The most recent ADA guidelines emphasize the importance of individualizing the nutrition prescription to meet specific goals of therapy for each patient, and allow for more variation in proportion of energy from carbohydrate and fat and limited variation in protein intake (10–20%), depending on individual needs. The focus for carbohydrate intake shifted away from restriction of sugar, or sucrose, to the total amount of carbohydrate included in the diet. Based on scientific evidence, sucrose can be incorporated into the meal plan as a part of an overall healthful diet.¹ In recognition of the difficulty of the task of nutritional management of patients with diabetes, the concept of a coordinated team approach was expanded to include an active role for the patient.

NUTRITION RECOMMENDATIONS

Energy Needs

The most important decision for nutrition management in patients with diabetes involves deciding the appropriate total energy intake, which may differ from patient to patient (Tables 26-3 and 26-4).⁷ During childhood and adolescence, patients with type 1 diabetes mellitus (T1DM) need extra energy for normal growth and development. Pregnant and lactating women also have increased energy demands, and total energy intake should be appropriately increased in such patients. Because most patients with type 2 diabetes mellitus (T2DM) are obese, usually total energy intake should be less than that needed for weight maintenance. After achieving reasonable body weight, it can be adjusted to maintain body weight and prevent future weight gain. However, in some instances, when patients with T2DM have lost considerable weight, such as at the time of diagnosis of diabetes mellitus or during chronic infections, severe illness, a postoperative period, or chronic severe hyperglycemia, they may in fact need extra energy beyond that needed for weight maintenance. Such patients lose not only body fat but also lean body mass that needs to be recovered.

TABLE 26-1 Goals of Medical Nutrition Therapy

- Maintenance of as near-normal blood glucose levels as possible by balancing food intake with insulin (either endogenous or exogenous) or oral glucose-lowering medications and physical activity levels
- Achievement of optimal serum lipid levels
- Provision of adequate calories for maintaining or attaining reasonable weights for adults, normal growth and development rates in children and adolescents, increased metabolic needs during pregnancy and lactation, or recovery from catabolic illnesses
- Prevention and treatment of the acute complications of insulin-treated diabetes such as hypoglycemia, short-term illnesses, and exercise-related problems, and of the long-term complications of diabetes such as renal disease, autonomic neuropathy, hypertension, and cardiovascular disease
- Improvement of overall health through optimal nutrition

TABLE 26-3 Estimating Energy Requirements for Adults

Basal energy requirements:	20–25 kcal/kg (80–100 kJ/kg) of desirable body weight
*Adjustment of additional energy required for activity level:	
Sedentary	30% of estimated basal energy requirements
Moderate	50% of estimated basal energy requirements
Strenuous	100% of estimated basal energy requirements
*Adjustments:	
During pregnancy (2nd and 3rd trimester)	Add 300 kcal (1250 kJ) per day
During lactation	Add 500 kcal (2100 kJ) per day
For weight gain (0.5 kg/wk)	Add 500 kcal (2100 kJ) per day
For weight loss (0.5 kg/wk)	Subtract 500 kcal (2100 kJ) per day

*Adjustments are approximate; weight changes should be monitored and compared to energy intake.

TABLE 26-4 Estimating Energy Requirements for Children and Adolescents

Age in Years	kcal(kJ)/kg body weight*
≤3	~100 (~400)
4–6	90 (375)
7–10	70 (300)
11–14 Males	55 (230)
15–18 Males	45 (190)
11–14 Females	47 (200)
15–18 Females	40 (165)

*Adjustments may be needed for activity level and other individuals variations.

Obesity is a major predisposing factor for T2DM; thus reduced energy intake is an important aspect of management for these patients as well as for prevention of diabetes in susceptible individuals. Some patients with T2DM are prone to truncal obesity as well as generalized excess body fat.^{8,9} Beyond the detrimental effects of overall adiposity, distribution of body fat, particularly in the truncal region, further predisposes subjects to insulin resistance. In addition, the threshold for developing insulin resistance in response to adiposity may vary in different ethnic groups as well among individuals belonging to the same ethnic group.^{8,10,11} Therefore, even mild increases in truncal subcutaneous fat and intra-abdominal fat can lead to insulin resistance in susceptible subjects. Patients who are not considered overweight by weight-for-height standards may have excess adiposity, and thus could also benefit from reduction of body fat. Interestingly, even small

amounts of weight loss (5–10%) can markedly improve glycemic control and serum lipid levels.^{12–15}

Controversy exists over whether high-carbohydrate or high-fat diets are more effective in causing weight loss. Studies show that if reduction of total energy intake is similar, the diets cause equal loss of body weight.¹⁶ On the other hand, studies conducted in the United States revealed that total energy consumption was higher on a high-fat diet compared to a high-carbohydrate diet.^{17,18} However, whether this excess energy intake on high-fat diets continues for the long term remains unclear. Since people in the United States tend to consume high-fat diets, whether other groups such as Asians or Africans who are habituated to high-carbohydrate diets will also tend to consume extra energy when given high-fat diets remains unclear. Therefore, the major emphasis should be on reduction of total energy intake.

Two approaches may be considered for reduction of total energy intake: a very-low-calorie diet (VLCD) or a low-calorie diet (LCD). The very-low-calorie diet (less than 800 kcal or 3350 kJ per day) will promote rapid weight loss and lead to reduction of blood pressure and serum glucose and lipid levels. The VLCD may be either a food-based plan or a liquid formula. To safely implement the VLCD, close medical supervision is required. Care must be taken to include adequate protein (1.0–1.4 g/kg of ideal body weight per day), vitamins, electrolytes, and fluids. Side effects of VLCDs include rapid loss of lean body mass, electrolyte imbalance, cardiac arrhythmias, gout, and gallstones. Less serious side effects include hair loss, anemia, cold intolerance, constipation, fatigue, and menstrual irregularities. VLCDs should only be used for those with body mass index (BMI) greater than 30 kg/m², not for mildly overweight individuals.¹⁹ There is some evidence that VLCDs may produce disordered binge eating in some people.²⁰ Even though short-term weight loss is greater on VLCDs, the long-term results (i.e., producing weight loss after 1 year) are no more effective than a low-calorie diet.²¹ The preferred approach to energy reduction is the LCD (800–1500 kcal or 3350–6300 kJ per day). This approach represents a reduction of 500–1000 kcal (2100–4200 kJ) per day to produce weight loss of 0.5–1 kg per week.²² However, reduction in energy intake of 1000 kcal (4200 kJ) per day, a significant change in food habits for most individuals, can be difficult to sustain for an extended period of time.

An alternative approach is to reduce energy intake by 250–500 kcal (1050–2100 kJ) per day to promote gradual weight loss of approximately 0.25–0.5 kg per week.¹ Gradual changes in types of foods and moderate reduction in portion size can lead to gradual weight loss that is more likely to be sustained over the extended period most obese individuals will need to achieve their goal weight.

Some people claim that high-protein, low-carbohydrate diets promote weight loss. They suggest that carbohydrate intake, by stimulating insulin secretion, contributes to insulin resistance, obesity, and other metabolic abnormalities, and therefore should be reduced. However, such diets have not been investigated clinically. Proposed benefits of the low-carbohydrate diet are initial rapid weight loss and short-term improvements in serum lipids. The low-carbohydrate intake of some of these diets leads to induction of ketosis. Studies of ketogenic diets used to control seizures in children have reported adverse effects such as an increased risk of kidney stones, as well as constipation and dehydration. Other relevant but less common side effects associated with use of ketogenic diets include hyperlipidemia, impaired neutrophil function, osteoporosis, and optic neuropathy.^{23,24} Very-low-energy ketogenic diets have also been reported to have a negative effect on cognitive function.²⁵

High protein intake can lead to hypercalciuria, hyperuricemia, an hypocitraturia that can contribute to kidney stone formation, gout and possible reduction in bone density.^{26–29} Most individuals can tolerate unlimited intake of high-protein, high-fat foods for only short time, leading to decreased total energy intake and thus weight loss. The limited variety of food allowed also contributes to decreased energy intake. In addition, decreased intake of vitamin and minerals may be deleterious.

Macronutrients

After deciding total energy intake, the patient and the dietitian should consider the choice of macro- and micronutrients.

Dietary Carbohydrates

Traditionally, intake of complex carbohydrates has been recommended for patients with diabetes, and intake of simple carbohydrates (mono- and disaccharides) such as glucose, fructose, and sucrose is discouraged. This is based on the notion that simple sugars are more rapidly absorbed and therefore can cause wide fluctuations in blood glucose. Equal energy intake from complex carbohydrates such as starch or naturally occurring simple carbohydrates causes similar increases in plasma glucose concentrations.^{2,30–32} Fructose causes a reduced glycemic excursion.^{35–37} However, sucrose or fructose intake may increase serum triglyceride and cholesterol concentrations compared to starch intake, although results have been inconsistent.^{38–41} Therefore, while small amounts of simple sugars can be ingested as part of a healthful diet, overall intake should be limited.⁴²

Nutritive sweeteners, including honey and fructose, may not have any advantage or disadvantage over sucrose.^{1,2} While sucrose and other refined sugars can be substituted for other carbohydrates in the meal plan, caution is still needed. Foods containing sugars are also often high in fat as well as energy. Fruit as a source of fructose is not of concern as long as total carbohydrate intake is controlled; however, high-fructose corn syrup, which is added to many foods and beverages today, should be limited.^{35,43}

Sucrose can increase palatability and thus interfere with weight loss efforts. It can also contribute to the development of dental caries. The amount of carbohydrate in the meal plan should be based on an assessment of current intake and must be individualized. Patients who are using oral antidiabetes agents or insulin need to maintain day-to-day consistency and meal-to-meal consistency in the amount of carbohydrate consumed to maintain good glycemic control. Some experts advise dietary carbohydrate-based calculation of insulin dose in patients with T1DM. Complex carbohydrates should be encouraged and simple sugars from fruits and vegetables are preferred because of the vitamins, minerals, and other nutrients in those foods.

The glycemic index of foods has been proposed as a criterion to select carbohydrate-containing foods.⁴⁴ The glycemic index is a ranking of foods based on their immediate effect on an individual's blood glucose levels. Following ingestion of a 50-g carbohydrate portion of a food, the blood glucose concentration area under the curve above the fasting glucose concentration is compared with the blood glucose area obtained with 50-g carbohydrate portion of white bread or glucose.⁴⁵ Interestingly, bread, some cereals, and potatoes have a higher glycemic index than simple sugars. Lower-glycemic foods include pasta, unprocessed grain products, legumes, dairy products, and some fruits. Several factors, including differences in cooking methods and processing, molecular and

physical characteristics of the starch in the product, and individual variations in blood glucose response, can affect glycemic index.⁴⁶ Further, long-term intake of low-glycemic-index foods has not shown consistent improvement in plasma glucose or lipid concentrations in patients with diabetes.^{47,48} Therefore, many experts, including the ADA, do not recommend the use of the glycemic index in nutritional management of patients with diabetes.

Sweeteners

Sugar alcohols (or polyols) such as sorbitol, mannitol, lactitol, and isomalt provide 2–3 kcal (8–12 kJ) per gram (Table 26-5). Hydrogenated starch hydrolysates and polyols are often used in sugar-free candies and cough drops. All of the polyols can cause significant gastrointestinal distress (cramping and diarrhea) if consumed in large amounts (20–50 grams, depending on the product). Small children may be particularly susceptible to developing diarrhea resulting from ingestion of as little as 0.5 g/kg body weight of polyols.⁴⁹ Sugar alcohols should not be used to treat hypoglycemia.

Non-nutritive sweeteners include saccharin, aspartame, acesulfame K, and sucralose. Both saccharin and acesulfame K are excreted unchanged from the body and provide no energy. Saccharin has been found to cross the placenta and is cleared slowly by the fetus; therefore, its use in pregnancy is not recommended.⁵⁰ Although aspartame contains 4 kcal (17 kJ) per gram, it is consumed in very small amounts, and thus contributes a negligible amount of energy. Aspartame cannot be used in cooking due to heat instability. People with phenylketonuria should not use aspartame because its metabolism yields phenylalanine. Sucralose (trichlorogalactosucrose) is being used in certain products such as fruit juice and pie fillings, with a substantial reduction in energy in those items. Sucralose provides no energy, is heat stable, and can be used in desserts, confections, and beverages.⁴³ The commercial version of sucralose (Splenda®) is packaged with a small amount of dextrose, thus contributing a minimal amount of energy.

Protein

Adequate protein intake is necessary for maintenance of lean body mass in adults. Children have higher protein needs to support

growth, as well as for maintenance. Protein needs are also increased during pregnancy, lactation, catabolic illness or stress, and during vigorous exercise. Typical intake of protein in the United States ranges from 15–20% of total energy, while the recommended dietary allowance (RDA) for protein is approximately 10% of total energy (0.8 g/kg).⁷ Protein intake of 10–20% of total energy is recommended by the ADA, and this will meet protein needs in most situations.³ When using reduced energy diets, it is especially important to include adequate protein.

Reduction of protein intake to 0.8 g/kg is recommended for patients with chronic renal insufficiency and diabetic renal disease; however, protein malnutrition can occur on lower intakes.⁵¹ Although studies suggest that decreasing protein intake in people with T1DM may delay the progression of nephropathy, it is not clear if all patients with diabetes would benefit from reduced protein intake.^{52,53} In addition, it is unclear whether protein from different sources, e.g., from meat, vegetables, eggs, or milk, has variable effects on renal function.^{54–56}

Good sources of protein include meat, poultry, fish, dairy products, legumes such as soybeans, chickpeas, other seeds and nuts, grain products, and vegetables. Because meat, poultry, and dairy products tend to be major sources of saturated fat and cholesterol, lower-fat selections should be made. Besides supplying protein, dairy products are excellent sources of calcium, and red meats are good sources of iron and zinc. Consumption of 500 mL (~2 cups) of milk and 140–170 g of meat, poultry, or fish per day can provide approximately 20% of total daily energy requirements from protein in adults. In contrast, a lacto-ovo vegetarian diet provides about 12–14% of energy from protein, while vegan diets provide about 10–12% energy from protein.⁵⁷ Although soy protein has some serum cholesterol-lowering effects, the mechanisms remain unclear. Whether protein from other legumes will have similar cholesterol-reducing potential has not been established.

Dietary Fats

Dietary fats, or triglycerides, usually contain a mixture of saturated (no double bonds), monounsaturated (one double bond), and polyunsaturated (two or more double bonds) fatty acids. Mono-

TABLE 26-5 Comparison of Sweeteners

Compound	Energy (kcal/kg)	Relative Sweetness Compared to Sucrose
Sucrose	4.0	1.0
Fructose	4.0	1.2–1.8
Sugar alcohols (polyols)		
Erythritol	0.2	0.7
Hydrogenated starch hydrolysates	3.0	0.25–0.5
Isomalt	2.0	0.45–0.65
Lactitol	2.0	0.3–0.4
Mannitol	1.6	0.5
Sorbitol	2.6	0.5–0.7
Xylitol	2.4	1.0
Non-Nutritive Sweeteners

Source: American Dietetic Association.⁴³

and polyunsaturated fatty acids can be further classified as *cis* or *trans* depending on the geometric configuration of the double bonds. Approximately 90% of total fat intake in the United States comes from fats and oils, red meat, poultry, fish, and dairy products. Two-thirds of the saturated fat in the diet comes from animal fats, emphasizing the need to limit the quantity of animal products eaten. Invisible or hidden fats and oils are often overlooked. The importance of reducing cholesterol-raising fatty acids (mainly the saturated and *trans* variety) in the diet to achieve maximum reduction in serum low-density lipoprotein (LDL) cholesterol is well established. The goals for serum lipid and glycemic control may be used as the basis for individualization of the amount of fat included in the diet.

Saturated Fatty Acids

Saturated fatty acids should be limited to <10% and preferably to <7% of total energy.^{3,58} The saturated fatty acids with the most potent serum cholesterol-raising effect are lauric (C12:0; 12-carbon chain length and no double bonds), myristic (C14:0), and palmitic (C16:0) acids.⁵⁹ Stearic acid (C18:0) does not raise serum LDL-cholesterol.^{60,61} Recent studies have found that the medium-chain fatty acids caprylic (C8:0) and capric (C10) acids, as well as the long-chain fatty acid behenic acid (C22:0), also raise serum LDL-cholesterol.^{62,63}

Polyunsaturated Fatty Acids

Polyunsaturated fatty acids should also be limited to 10% or less of total energy intake.^{3,58} Polyunsaturated fatty acids are classified as n-6 (ω -6) or n-3 (ω -3), depending on the location of the first double bond counting from the methyl end of the carbon chain. Consumption of approximately 2–3% of total energy intake from n-6 polyunsaturated fatty acids supplies adequate amounts of essential fatty acids. The essential fatty acids are linoleic acid (n-6, C18:2) and α -linolenic acid (n-3, C18:3). Arachidonic and γ -linolenic acids can be formed from linoleic acid. Linoleic acid, when substituted for saturated fatty acids, lowers LDL-cholesterol, but does not decrease triglycerides. Large intakes of linoleic acid, however, may decrease HDL-cholesterol concentrations.⁶⁴

Omega-3 (n-3) fatty acids have been shown to reduce serum triglycerides by competitively inhibiting hepatic triglyceride synthesis. Fish oils are the major sources of eicosapentaenoic acid (C20:5) and docosahexaenoic acid (C22:6). Fish oil intake in large quantities (up to 5–10 g of n-3 polyunsaturated fatty acids per day) can cause hyperglycemia by increasing hepatic glucose output.⁶⁵ Such adverse effects, however, have not been noted with small doses of fish oil and when energy intake is adequately controlled.⁶⁶ Fish oils can also raise serum LDL-cholesterol concentrations, particularly in patients with hypertriglyceridemia.^{67,68} Reduced risk of

acute myocardial infarction as a result of decreased platelet aggregation could be another potential benefit of n-3 fatty acids. For patients with diabetes, the increase in consumption of n-3 fatty acids should be via increased intake of fish, except in those with hypertriglyceridemia, who need moderate to large doses of fish for reduction of serum triglycerides.

cis-Monounsaturated Fatty Acids

The *cis*-monounsaturated fatty acids are abundant in natural foods. People from Mediterranean countries who consume diets rich in *cis*-monounsaturated fats have lower mortality rates, particularly from coronary heart disease. Recent studies have shown that when oleic acid (C18:1) is substituted for saturated fatty acids, serum LDL-cholesterol declines just as much as with polyunsaturated fatty acids.^{69–74} A preliminary study showed that erucic acid (C22:1) may also have cholesterol-lowering properties similar to those of oleic acid, but little is known about the effects of other *cis*-monounsaturated fatty acids such as palmitoleic (C16:1) and gadoleic (C20:1) acid.⁷⁵ This led us to explore potential beneficial effects of *cis*-monounsaturated fatty acids for patients with T2DM.

In a randomized, crossover study in patients with T2DM compared to a high-carbohydrate diet, a diet high in *cis*-monounsaturated fatty acids, with reduced plasma triglyceride and very-low-density-lipoprotein (VLDL) cholesterol levels, raised high-density lipoprotein (HDL) cholesterol and apolipoprotein A-I concentrations, but caused no changes in plasma total cholesterol, LDL-cholesterol, and apolipoprotein B. The high-*cis*-monounsaturated-fat diet also lowered plasma glucose and insulin concentrations.⁷⁶ A recent meta-analysis of nine randomized crossover trials showed that compared to high-carbohydrate diets, the high-*cis*-monounsaturated-fat diets reduced fasting plasma triglyceride by 19% and VLDL-cholesterol concentrations by 22%. A modest increase in HDL-cholesterol was noted with no adverse effect on LDL-cholesterol concentrations (Table 26-6).

Besides beneficial effects of diets rich in *cis*-monounsaturated fatty acids on serum lipids and glycemic control, such diets may increase compliance for some individuals used to a high-fat diet. When weight loss is a goal, attention should be given to overall energy intake. Good sources of *cis*-monounsaturated fatty acids include canola, olive, mustard, and peanut oils, avocados, olives, and some nuts (Table 26-7).⁷⁸ Certain genetically modified varieties of safflower and sunflower oils are also rich in *cis*-monounsaturated fatty acids.

trans-Fatty Acids

Partial hydrogenation of oils yields a firmer and more stable product than the original oil, but the process also leads to formation of *trans*-fatty acids.

TABLE 26-6 Net Change in Lipids and Lipoprotein Concentrations in Type 2 Diabetic Patients with the High Monounsaturated Fat Diet, as Compared with the High Carbohydrate Diet*

Parameter	Total Cholesterol	Triglycerides	VLDL Cholesterol	LDL Cholesterol	HDL Cholesterol
No. of studies	9	9	4	6	9
No. of subjects	133	133	68	105	133
Change in mmol/L*	-0.15	-0.36	-0.20	-0.01	+0.05
(95% CI)	(-0.24 to -0.06)	(-0.43 to -0.29)	(-0.24 to -0.15)	(-0.10 to +0.08)	(+0.03 to +0.07)
Percent change*	-3.0	-19.0	-22.5	0.0	+4.0

*Results of a meta-analysis of nine studies. Net or percent change is expressed as the concentration during the high monounsaturated fat diet minus that during the high carbohydrate diet.⁷⁷

CI, confidence interval; VLDL, very-low-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

TABLE 26-7 Various *cis*-Monounsaturated Fatty Acids and Their Dietary Sources

Common Name	Notation	Sources
Lauroleic	C12:1	Fish oils
Myristoleic	C14:1	Fish oils, beef fat
Palmitoleic	C16:1	Fish oils, beef and pork fat
Oleic	C18:1	<i>Oils:</i> olive, canola, ground nut (peanuts), high-oleic safflower and sunflower, avocado, aceituno, shea nut, rice bran, sesame, <i>Jessenia bataua</i> , tea seed <i>Nuts:</i> filberts, almonds, pistachios, pecans, macadamias, cashews <i>Others:</i> mowrah butter; illipe butter; *fat of cattle, pigs, goats, chicken, and sheep; *cocoa butter
Gadoleic	C20:1	Fish oils (such as herring, sardines, mackerel), jojoba oil
Erucic	C22:1	Mustard seed oil, rape seed oil, nasturtium seed oil

*Although a source of oleic acid, these fats should be used sparingly because they are high in cholesterol-raising saturated fatty acids.

Source: Padley, *et al.*⁷⁸

of *trans*-monounsaturated or *trans*-polyunsaturated fatty acids. Partially hydrogenated oils are often used as a substitute for saturated fats in foods such as spreads, shortenings, and baked goods. Approximately 3% of the total daily energy is provided by *trans*-fatty acids in the United States.⁷⁹ In other western countries 0.5–2.1% of the total energy consumption is from *trans*-fatty acids.⁸⁰ Dietary *trans*-fatty acids should be limited as much as possible because they have been shown to raise serum LDL-cholesterol and apolipoprotein B levels and may lower serum HDL-cholesterol and apolipoprotein A-I.^{81,82} Furthermore, intake of *trans*-fatty acids has also been associated with higher risk of coronary heart disease.⁸³

Fat Replacers

Fat replacers can help to lower overall fat intake; however, these products cannot counteract the effects of a diet high in fat and cholesterol. Patients may need education in label reading to understand the difference between reduced-fat, low-fat, and fat-free products. Fat replacers are of questionable benefit in weight management, as many have only slightly reduced energy than the regular product. In addition, satiety value may be less for the reduced-fat product, leading to increased overall intake.

Fat replacers can be made from carbohydrates, proteins, or fat.⁸⁴ Carbohydrate-based fat replacements are gums, gels, and maltodextrins that add creaminess and texture to foods such as salad dressings. A significant amount of carbohydrate may be consumed in a low-fat product made with a carbohydrate-based fat replacement, especially if the serving size listed on the label is small. Protein-based fat replacers are made of microparticulated egg white or milk protein. They can be used in cheese, salad dressings, and some baked products. Most protein-based fat replacers lose their desired effect due to coagulation when subjected to high temperatures, thus limiting the types of products in which they can be used. Protein-based fat replacers add 1–4 kcal (4–16 kJ) per gram.⁸⁴ Fat-based substitutes are either synthetic or modified fats. Olestra, a sucrose polyester, is a synthetic fat that is not digested or absorbed and thus contributes no energy. Large amounts of olestra can cause gastrointestinal distress and may reduce absorption of fat-soluble vitamins.⁸⁵ Salatrim[®] and caprenin are examples of fats altered to decrease absorption. Salatrim provides ~20 kJ (5 kcal) per gram and is a modified triglyceride containing acetic, propionic, and stearic acids. Caprenin also provides ~20 kJ per gram and contains caprylic (C8:0), capric (C:10), and behenic

(C22:0) acids. Even though absorption of caprenin and Salatrim is decreased, caprylic, capric, and behenic acids can raise serum cholesterol concentration.⁵⁹

Dietary Cholesterol

Both serum LDL- and total cholesterol are increased by high intake of dietary cholesterol. Limiting dietary cholesterol to 300 mg or less per day is recommended, while further reduction to 200 mg or less may be necessary to achieve maximal lowering of LDL-cholesterol. Animal products are the sole sources of dietary cholesterol, and their intake should be limited.^{1,58} Consumption of 140–170 grams per day of lean meat, poultry, or fish and 500–750 mL (2–3 cups) of nonfat or low-fat dairy products is recommended. Certain high-cholesterol foods, such as egg yolks and organ meats, should be limited. Egg yolks should be limited to 2–4 per week, including those used in cooking. Egg whites may be used in place of whole eggs. Certain shellfish (i.e., shrimp) have higher cholesterol content than other meats or fish, but may be consumed in moderation because of their lower saturated fat content.⁵⁸

Dietary Fiber

The recommended intake for dietary fiber for patients with diabetes is 20–35 grams per day, a significant increase over the usual intake of 16 to 17 grams per day in the United States.⁸⁶ In other Western countries fiber intake is also quite low, approximately 22 grams per day.⁸⁷ Dietary fiber can be classified as soluble or insoluble. Insoluble fibers such as cellulose, lignin, and some hemicelluloses increase stool volume and shorten intestinal transit time, but do not affect serum cholesterol levels. Soluble fibers such as pectin, gums, mucilages, and some hemicelluloses reduce serum cholesterol by approximately 5%.⁸⁸ A recent study in subjects with T2DM, comparing a diet high in total fiber (50 grams total fiber, 25 grams each of soluble and insoluble fiber) from foods unfortified with fiber supplements to a moderate-fiber diet (24 grams total, 8 grams soluble and 16 grams insoluble), reported a 10% reduction in 24-hour plasma glucose and a 12% reduction in plasma insulin levels, as well as decreased daily urinary glucose excretion (Fig. 26-1).⁸⁹ The high-fiber diet also reduced plasma cholesterol by 7%, triglycerides by 10%, and VLDL-cholesterol by 12.5%. Selection of such fruits, vegetables, and grains with a high proportion of soluble to insoluble fiber is recommended (Table 26-8).⁹⁰

FIGURE 26-1. Profile of 24-hour plasma glucose and insulin levels (means $\pm$ SEM) obtained on the last day of each diet period. The circles represent mean values on the American Diabetes Association (ADA) diet and the squares represent mean values on the high-fiber diet. The arrows indicate the times at which the major meals and a snack were consumed during the day. An asterisk denotes $p < 0.05$ for the ADA diet versus the high-fiber diet values. To convert values of plasma insulin to picomoles per liter, multiply by 6. (Modified with permission from Chandalia et al.⁸⁹)

Alcohol

The ADA recommends the same guidelines for alcohol consumption for patients with diabetes as those for the general population; however, there are some additional concerns.^{91–94} Pregnant women and people with a history of alcohol abuse, pancreatitis, gastritis, and certain other conditions should abstain from alcohol intake. One recent study reported increased risk for developing T2DM in men who abstain or drink large amounts of alcohol when compared with those who are moderate drinkers.⁹⁵ Low to moderate alcohol intake on a regular basis in nondiabetic subjects can increase serum HDL-cholesterol and apolipoprotein A-I levels, thus contributing to lower cardiovascular risk; however, these effects are somewhat negated by an accompanying increase in blood pressure and decrease in concentration of antithrombin III.⁹⁶ In large amounts, alcohol causes peripheral insulin resistance, and may lead to hyperglycemia, hypertriglyceridemia, and hypertension.^{97–99} Alcohol may also contribute to development of truncal obesity and fatty liver.^{100–102} Because alcohol ingestion may enhance glucose-stimulated insulin secretion and reduce gluconeogenesis, binge drinking and/or failing to consume food with alcohol increases the likelihood of hypoglycemic events. The likelihood of hypoglycemic unawareness also increases with alcohol ingestion. To reduce the risk of hypoglycemia when insulin is required, food should never be omitted to compensate for the alcohol consumed

and meals must be eaten at the scheduled times.^{1,103,104} People with T2DM, particularly elderly individuals, who drink alcohol and require oral antidiabetes agents are also at increased risk for hypoglycemia, but their risk is less than that for T1DM.¹⁰⁵ With good glycemic control, moderate ingestion of alcohol (two drinks men and one for women) has limited acute effect on blood glucose levels. Alcohol provides 7 kcal (30 kJ) per gram and in T2DM where weight management is usually a concern, energy from alcohol should be substituted for fat energy.

Micronutrients

Vitamins

There is little need for vitamin and mineral supplementation in patients who eat a variety of foods and consume adequate energy to maintain body weight.¹⁰⁶ Patients following reduced-energy diets for long periods of time, however, can be at risk for consuming less than the recommended intake of some nutrients. In addition, the individuals who consume meals or snacks prepared away from home are more likely to have diets lower in vitamin and mineral content than those who consume more conventional meals prepared in the home. During pregnancy and in times of illness and stress, nutrient needs are increased. A thorough assessment of a patient's current diet by a dietitian can be helpful to determine if supplementation may be indicated.

Because of increased risk for coronary heart disease in people with diabetes, the antioxidant vitamins such as vitamins C and E are of particular interest. They may protect LDL-cholesterol particles from oxidation or modification, but clinical trials that support the benefits from the effects are lacking.^{107,108} In fact, a recent large clinical trial evaluating cardiovascular outcomes found no positive effect for vitamin E supplementation.¹⁰⁹ Earlier enthusiasm for the antioxidant beta-carotene has declined after reports of either no beneficial effect or slightly increased risk for lung cancer in subjects who took beta-carotene supplements.^{110,111}

Minerals

Chromium

Chromium is often touted as a mineral that needs to be supplemented in diabetes because it is a component of glucose tolerance factor. However, unless the diet is deficient in chromium, its supplementation does not improve glucose tolerance.^{112,113}

Magnesium

Magnesium serves many important functions in the body. Patients with diabetes tend to have low blood magnesium levels, most likely due to urinary loss of magnesium associated with chronic glycosuria.^{114–116} However, repletion with oral magnesium chloride is recommended only for those who have documented hypomagnesemia. Good food sources of magnesium include liver, leafy green vegetables, legumes, and nuts. Those who follow a nutritionally balanced meal plan and consume adequate energy should be able to obtain adequate magnesium from their food.¹¹⁷

Sodium

Scientific evidence strongly supports the effectiveness of good blood pressure control to prevent complications of diabetes, and reduction of sodium intake has been found to be effective in lowering blood pressure in subjects with hypertension.^{118–120} Older individuals, especially those with diabetes, appear to be more sensitive

TABLE 26-8 Fiber Content of Some Foods Particularly Rich in Soluble Fiber

sodium than others.¹²¹ For individuals with hypertension, moderate restriction of sodium (2400 mg/d) is usually recommended.¹²² Patients with diabetic nephropathy should limit intake of sodium to ≤ 2000 mg per day.³ Acute severe sodium restriction (< 500 mg/d) has been shown to adversely affect serum total and LDL-cholesterol and to increase resistance to the vasodilating effects of insulin.^{123–125} For older individuals who are thin or at normal body weight, severe sodium restriction may adversely affect energy intake due to decreased palatability of food and thus could contribute to malnutrition. Dietary intake of sodium usually greatly exceeds the minimum needed for normal body function due to its frequent use in foods such as canned soups, salty snacks, and processed meats. Meals and snacks purchased in restaurants are also likely to have a higher sodium content than meals prepared from fresh foods at home. Reduction of sodium intake can be difficult to achieve unless the diet is based primarily on fresh rather than processed foods.

Phytochemicals and Supplements

Evidence is growing in support of increased intake of fruits and vegetables in the diet as more is learned about potential health benefits of newly identified substances in those foods. Isoflavones are an example of phytoestrogens found in vegetables, fruits, and legumes. Some potential beneficial effects of isoflavones, such as genistein and daidzein from soy products, include antioxidant properties, weak estrogenic effects, and action as modulators of intestinal glucose transport.

Sitostanol, a plant sterol incorporated into margarine, lowers serum LDL-cholesterol by 10–15% in mildly hypercholesterolemic subjects by competitive inhibition of gastrointestinal absorption of cholesterol.^{126–128} It may be a useful dietary adjunct for patients with diabetes.^{129,130}

Other substances in plants, such as lutein, lycopene, lignans, and saponins, are currently being investigated and may eventually play a role in enhancing health. As studies are conducted using these substances, foods are emerging as the preferred source. The isolated individual components taken in the form of a supplement do not always have the same effect as the substance when consumed in a whole food along with all the other elements present in the food.

Use of botanical (herbal) supplements is widespread and growing among the general population and is especially prevalent among patients with chronic diseases.¹³¹ Clinical evidence to support the efficacy and safety of use of many of these products is very limited. Because of the potential for harmful effects and possible interaction with prescription medications, patients should be asked about their use of all types of supplements.

Meal Frequency and Timing

For patients with T1DM, consistency in timing of meals in relation to insulin action is important to prevent wide fluctuations in blood glucose levels. Adjustments should be made in the timing of insulin injections to match peak glucose excursion after meals and snacks.

As discussed earlier, consistency in the amount of carbohydrate eaten is of greatest importance, as dietary protein and fat have a lesser effect than carbohydrates on blood glucose levels. If there are more than 5 hours between meals, a snack may be needed to prevent a hypoglycemic event. Multiple daily injections or use of an insulin pump provides greater flexibility in timing of meals for the person with T1DM.

For patients whose diabetes is controlled by diet alone or with oral agents, eating 3–5 small meals per day may be beneficial. Although frequency of feeding does not appear to affect rate of weight loss when energy intake is constant, more frequent eating may lead to less fluctuation in satiety level, thus curbing the tendency to consume excessive energy.^{132,133} Patients taking oral agents to lower blood glucose levels should be advised to avoid skipping meals to prevent hypoglycemic events. Multiple small meals have been shown to have a positive effect on serum lipids and lipoproteins, insulin, and postprandial glucose when compared to a pattern of less frequent meals.^{133–135} In addition, less impulsive eating and a reduced dietary fat intake have been noted when breakfast is eaten.¹³⁶

SPECIAL ISSUES

Type 1 Diabetes Mellitus

Infants and Young Children

Providing adequate nutrition for normal growth and development and prevention of hypoglycemic events are two major goals in management of diabetes in infants and children. Children with poor glycemic control may grow at a slower rate. Growth should be monitored every 3–6 months so that appropriate intervention can be made if growth is not optimal. To help prevent hypoglycemia, blood glucose target goals for infants and children are higher than for adults. Preprandial target blood glucose ranges for infants and toddlers are 120–220 mg/dL, for preschool children, 100–200 mg/dL, and for school-age children, 70–150 mg/dL.¹³⁷ Because the risks of hypoglycemia are greater for infants and young children due to ineffective communication and brain growth, blood glucose should be monitored frequently. For infants, a flexible 3- to 4-hour feeding schedule of breast milk or iron-fortified formula can help to maintain normoglycemia. Other foods can be added to the diet at the usual recommended age (4–6 months) to help maintain glucose levels and provide other sources of carbohydrate. Careful blood glucose monitoring is needed due to the fluctuating activity level in infants.

Toddlers present special challenges, because their physical activity and eating habits are sporadic and spontaneous. Toddlers need three meals and three snacks, and usually are good judges of how much they need to eat. The focus of food intake should be the overall picture over a period of time, rather than concern over limited food choices on a day-to-day basis. The dosage and timing of insulin administration should be adjusted to match the amount of carbohydrate that has been consumed.

Adolescents

The adolescent years also present challenges in diabetes management from a physiologic as well as developmental perspective. Rapid growth and hormonal changes influence insulin needs. From a meal planning perspective, the importance of eating a consistent amount of carbohydrate on a regular schedule requires creativity. The use of the carbohydrate counting method for meal planning

can provide flexibility.¹³⁸ Since this method focuses on a single nutrient, it gives more options and allows the adolescent to include foods his or her peers are eating, but still maintain consistent carbohydrate intake for good glycemic control.

For children of normal weight, usual intake is a good base to determine nutrition needs and establish a meal plan. Extra energy intake may be needed for catch-up growth if the child has weight or experienced growth faltering prior to the time of diagnosis. If intensive glycemic control is implemented for adolescent excessive weight gain may become a problem. While children with T1DM are typically thin or even underweight at the time of diagnosis, with the increased prevalence of childhood obesity in the United States, approximately 25% of children diagnosed with T1DM are now obese.¹³⁹

Age-appropriate physical activity should be encouraged to help establish lifelong habits early and emphasize the benefits to overall good health as well as diabetes management. As children begin to participate in organized sports and other physical activities, periodic guidance by nutritionists is needed to adjust the meal plan so that additional carbohydrate and energy are planned to maintain good glycemic control.

Type 2 Diabetes Mellitus

Adults

When the focus of management for T2DM is on improving serum glucose, hypertension, and lipid levels rather than on weight loss, there is greater incentive for continued and long-term changes. However, long-term maintenance of reduced weight is problematic for many individuals. Studies of those who have successfully maintained reduced weight reveal that continued self-monitoring by keeping food records and weighing themselves regularly is important.^{140–142} Increased physical activity, however, seems to be a key factor in maintenance of reduced weight.^{143–145} In addition to increased energy expenditure, physical activity seems to provide a sense of self-efficacy in overall weight management efforts.^{146,147} For lifelong adherence to a physical activity regimen, a person needs to find something enjoyable to do in order to increase the likelihood of continued activity.

Coronary heart disease, peripheral vascular disease, foot problems or amputation, osteoarthritis of hip or knee, and cerebrovascular accidents may limit patients' physical activity. A number of medications can adversely affect weight loss efforts. Tricyclic antidepressants and antihistamines may increase appetite. Nonsteroidal anti-inflammatory drugs as well as aspirin (even at prophylactic doses used for coronary heart disease and cerebrovascular disease) can cause gastritis. Energy balance can be affected by beta-blockers that can cause a slight decrease in metabolic rate.¹⁴⁸

Children and Adolescents

The prevalence of T2DM in children and adolescents is growing at an alarming rate, up from 1–2% in the past to recent reports of 8–25% of diabetes cases in children.¹³⁹ The increasing prevalence of obesity among children in the United States is likely a contributing factor to the increase in T2DM in this group. Except when life-threatening comorbidities exist, the goal for weight management in younger children is to maintain weight while providing adequate energy for continued linear growth. Modest energy restriction to promote weight loss in adolescents who are past the growth spurt is appropriate. When weight loss is indicated, energy intake should be reduced as discussed previously; however, increased physical activity should be stressed. Decreased physical activity has been

implicated as a major factor in development of obesity in children. As for adults, it is equally important that children find an activity they like and will continue to do over the long term. Family involvement is extremely important in promoting healthy weight in children.

Pregnancy and Lactation

Good diabetes management is essential for successful pregnancy outcome for a woman with diabetes. Nutritional planning 3–6 months prior to conception is essential to achieve near-normal glycemic control before and during pregnancy. Increased energy should be provided during pregnancy and lactation. The increased energy intake needed for development of the fetus and maternal tissue is approximately 300 additional kcal (1250 kJ) per day during the second and third trimesters of pregnancy.¹⁴⁹ Women with a body mass index of >26 to 29.0 kg/m^2 should gain 7–11.5 kg, while women with BMI $>29.0 \text{ kg/m}^2$ should gain ~ 7 kg. Protein intake should be increased by 10 grams per day. Folic acid, calcium, and iron should be increased appropriately.

Approximately 4% of women develop gestational diabetes. They are often overweight and are at increased risk for future development of T2DM. Energy restriction during pregnancy is controversial. Severe energy restriction can result in ketosis and can adversely affect the fetus. However, energy consumption of 1600–1800 kcal (6700–7500 kJ) per day can improve hyperglycemia without causing ketosis.^{150,151} Some experts recommend 30 kcal/kg of present pregnant weight for normal-weight women, 24 kcal/kg for overweight women, and 12 kcal/kg for morbidly obese women.¹⁵² To control postprandial glucose response, carbohydrates are limited to 40% of total energy intake and are distributed into three meals and three snacks. If an energy-restricted diet is used during pregnancy, adequate protein must be provided because pregnant women with diabetes may be more susceptible to protein malnutrition than those without diabetes.^{153–155} Weight loss efforts should continue during the postpartum period with a long-term goal of gradual weight reduction.

Consistent patterns of food intake and physical activity are important during pregnancy to avoid ketonemia and maintain stable blood glucose levels. Frequent meals and snacks may be eaten. Blood glucose levels in nondiabetic women are generally lower during pregnancy. Morning sickness can increase the likelihood of hypoglycemia. As the pregnancy progresses, increasing insulin resistance affects blood glucose levels and insulin needs. Carbohydrate intake should be adjusted to approximately 40–45% of total energy to maintain glycemic goals.¹⁵⁶

Breastfeeding should be encouraged, particularly for obese women with T2DM, as it can assist in their efforts to lose weight. Approximately 500 kcal (2100 kJ) per day are needed to provide the extra energy required for lactation. Because breastfeeding lowers blood glucose levels, the dose of insulin may be reduced appropriately and additional energy may be consumed, particularly during the night. Moderate weight loss can occur on energy consumption of approximately 35 kcal/kg of body weight as the maternal stores laid down during the pregnancy are used to support lactation. Weight loss of 0.5–1.0 kg per month is acceptable and up to 2 kg weight loss per month does not appear to compromise milk volume.^{157,158}

Eating Disorders

The prevalence of eating disorders, clinical and subclinical, among people with diabetes is at least as great as in the general population,

and some studies report higher rates.^{159–161} Eating disorders can significantly complicate short- and long-term diabetes management. Mostly young females, who tend to have greater concern about body weight and shape, are affected. Omission or reduction of insulin to control weight may be practiced by up to 30% of females with diabetes.^{159,162} Those who omit insulin are more likely to exhibit disordered eating, have a greater fear of hypoglycemia, report more psychological distress, and have poorer adherence to diabetes management protocols, leading to increased diabetes-related hospitalizations.¹⁶² Most studies report poorer glycemic control when disordered eating is present. Binge eating and purging are the most commonly reported types of disordered eating among patients with diabetes.^{161,163} Women who intentionally omit or reduce insulin dosage tend to have elevated plasma triglycerides, cholesterol, and hemoglobin A_{1c} concentrations, which may increase the risk for long-term complications of diabetes such as retinopathy and neuropathy.¹⁶⁴ Those who report bulimic behavior have an increased intake of energy, dietary fat, and cholesterol compared with those who do not.¹⁶⁵ In a German study that included subjects with T2DM, binge eating disorder often preceded the diagnosis of diabetes, possibly contributing to the obesity associated with T2DM.¹⁶⁰

Acute and Chronic Illnesses

Sick Day Guidelines

Nutritional management during acute illnesses requires adequate fluids (orally or intravenously) to avoid dehydration and at least 150 grams of carbohydrates to avoid ketosis. When solid food is not tolerated, energy can be provided in the form of liquids, such as juice, lemonade, sodas, gelatin, soup, ice cream, or sherbet.

Metabolic stress and pain during surgery or trauma increases circulating counterregulatory hormones and can lead to hyperglycemia. During such periods, it is extremely important to monitor and maintain appropriate fluid and electrolyte balance, metabolic control, and body weight. The nutritional goal during periods of stress is to avoid over- and underfeeding. Overfeeding further exaggerates the hyperglycemia caused by metabolic stress. Maintenance of blood glucose levels between 100 and 200 mg/dL is recommended to limit extremes of hypo- and hyperglycemia.¹⁶⁶ Impaired wound healing has been observed when blood glucose exceeds 200 mg/dL.¹⁶⁷ Adequate pain management is important, but the sedating effects of pain medication can increase risk of hypoglycemia.

Enteral and Parenteral Nutrition Support

The indications for such nutritional support for patients with diabetes are similar to those without diabetes. Energy and protein needs should be determined based on thorough nutrition assessment. Unintentional weight loss of 10–20% in a 6-month period suggests moderate malnutrition and $>20\%$ weight loss indicates severe malnutrition. Protein catabolism is often a consequence of the metabolic stress of severe illness or injury. Protein needs can usually be met with 1.0–1.5 g protein/kg body weight, but some patients may require higher protein intake. Monitoring of blood glucose and urine ketones is recommended every 6 hours during enteral nutrition and every 4 hours during parenteral nutrition.¹⁶⁸

Enteral Nutrition

Enteral nutrition is preferred if the gut is functioning because of less expense and fewer complications, and because it is more

physiologic and may have beneficial trophic effects on the gastrointestinal cells. Enteral nutrition is best supplied by commercially prepared formulas to limit risk of contamination; however, with careful attention to sanitation, nutritionally adequate formulas can be prepared by blending together milk and other foods. If the patient is lactose intolerant, cooked, pureed meat can provide the protein needed. Adequate liquid must be added to provide the proper consistency to avoid clogging of the feeding tube. Reduced fluid intake and high-carbohydrate formulas may increase risk of hyperosmolar nonketotic coma.

Total Parenteral Nutrition

Total parenteral nutrition (TPN) is recommended when oral intake is not adequate and enteral nutrition is not feasible. Accurate intake and output records are essential. Excess administration of glucose (>5 mg/kg body weight/min) may cause hyperglycemia and require a higher dose of insulin for good glycemic control. Continuous infusion of fat emulsion is recommended to maintain approximately 30% of energy intake (not greater than 2.5 g/kg body weight).¹⁶⁸ Use of lipid emulsions may need to be reduced or discontinued if serum triglyceride concentrations exceed 400 mg/dL.¹⁶⁶

Other Complications

Chronic Pancreatitis

Chronic severe pancreatitis can lead to destruction of the pancreas and subsequent development of diabetes. In addition, loss of exocrine function due to pancreatitis or pancreatectomy causes malabsorption. With adequate enzyme replacement therapy, greater intake of fat can be allowed with alleviation of fat and protein malabsorption.¹⁶⁹

Diabetic Nephropathy

Adjustments in dietary protein intake may help to slow the progression of diabetic nephropathy. In chronic renal insufficiency, a reduction in dietary protein to 0.8 g/kg is recommended.² The recommendation for protein intake in patients with nephrotic syndrome is also 0.8 g/kg. When protein intake is less than 0.8 g/kg, patients are at greater risk for malnutrition.¹⁷⁰ Adequate energy intake in the range of 35–40 kcal/kg may be needed in some instances to maintain body weight.¹⁷¹ Increased use of simple carbohydrates and unsaturated fats may be needed to achieve the desired level of energy intake. Hyperphosphatemia in chronic renal failure requires reduction of phosphorus intake to prevent metabolic bone disease. Intake of sodium and potassium must be monitored and adjusted as needed to maintain appropriate serum concentrations. Fluid intake must also be adjusted as renal failure progresses. As much as 80% of the dextrose in the dialysate used for peritoneal dialysis is absorbed and thus can contribute a significant amount of energy. Supplementation of certain vitamins and minerals may be needed due to the metabolic alterations of renal failure as well as poor dietary intake.

Autonomic Neuropathy

Gastroparesis

Gastroparesis is a complication of diabetes with significant nutrition and diabetes management implications. The symptoms of bloating, fullness, early satiety, nausea and vomiting, and abdominal pain can lead to decreased intake and weight loss. At the same

time the patient may experience postprandial hypoglycemia a fluctuating plasma glucose levels. Optimal glycemic control is important because hyperglycemia can slow gastric emptying. Nutritional management for gastroparesis includes (1) small frequent meals, (2) a low-fat, low-fiber diet, (3) use of foods of soft consistency, and (4) replacement of solid foods with liquid meals.¹⁷² Eating meals with more solid foods earlier in the day, then switching to liquids later in the day seems to help some patients. While it usually slows gastric emptying, many patients can tolerate fat in liquid form, such as milkshakes. Patients should be instructed to stop eating and drinking during and after meals. If enteral feeding is necessary, a jejunostomy feeding route is recommended.¹⁷³

Diarrhea and Constipation

Diabetic diarrhea occurs in approximately 10–20% of patients with poorly controlled diabetes. Before diagnosis of diabetic diarrhea can be definitively established, pancreatic insufficiency, bacterial overgrowth, lactose intolerance, or gluten-induced enteropathy must be considered as possible causes of persistent diarrhea. Constipation is another common complaint that occurs in patients with diabetes. Adjustments in diet have not been very effective in management of diarrhea or constipation that results from diabetic autonomic neuropathy; therefore, good glycemic control for prevention of development of neuropathy is essential.¹⁷⁴

Gluten-Induced Enteropathy

Celiac disease, or gluten-induced enteropathy, is a disease with a reported higher incidence (estimated at 1–8%) among patients with T1DM.^{175–177} Patients with celiac disease usually present with abdominal distention, diarrhea, weight loss (or failure to thrive in children), lactose intolerance, fatigue, and irritability. Depending on the severity of the gluten sensitivity and length of time prior to diagnosis, the patient may be at significant nutritional risk. The treatment requires avoidance of the protein gliadin and several other prolamins from the diet, which means elimination of wheat, rye, oats, and barley. Strict adherence to the diet results in significant improvement in symptoms but is difficult to achieve. The offending grains can be found in many products and are often hidden, making careful label reading essential. Nutrition advice should be obtained to plan nutritionally balanced meals for overall health.¹⁷⁸

OVERCOMING BARRIERS TO CHANGE

Barriers

Numerous obstacles to dietary compliance have been cited: a sense of isolation, time pressures and competing priorities, lack of support from friends and family, social events, negative emotions, and feelings of deprivation.¹⁷⁹ In a recent survey of dietitians who work with patients with diabetes, the greatest barrier to change identified was the complication of lifestyle and competing demands.¹⁸⁰ Included in this barrier category are (1) time constraints, (2) eating out, (3) lack of finances, (4) portion control, and (5) denial or unwillingness to make changes. The primary factors needed to overcome these barriers were individualization and simplification of meal plans and help with time management (scheduling). Medical nutrition therapy that involves assessment and individualized intervention has been shown to be effective in improving metabolic control in other studies as well.^{181,182} Physician referral for medical nutrition therapy in diabetes management is extremely important

due the difficulty in achieving dietary change. For approximately half of the patients with T2DM in one study, lack of physician referral was the reason for not consulting a dietitian.¹⁸³ Infrequent referral for dietary counseling was found to be as ineffective in facilitating dietary change as no referral.¹⁸⁴ The importance of following a meal plan for improved glycemic control in T1DM was recognized in The Diabetes Control and Complication Trial (DCCT).^{185,186} Increased adherence to meal plans occurs when patients attend follow-up nutrition counseling sessions.¹⁸⁷ Additional education about the complications of diabetes was identified as a means to overcome the barrier of denial or the perception that diabetes is not serious. Increased emphasis on blood glucose monitoring, more follow-up sessions, use of support groups, and further individualized education were recommended by dietitians involved in diabetes education.

Tools and Techniques

Practice guidelines have been developed to provide a systematic approach for provision of medical nutrition therapy for patients with diabetes mellitus. The major components of medical nutrition therapy are assessment, intervention, and evaluation. Intervention includes the nutrition prescription, education, and goal setting. For the intervention to be effective, the patient must be an active participant in this process.¹⁸⁸ Improved fasting plasma glucose, glycosylated hemoglobin, serum lipids, and body weight have demonstrated effectiveness of medical nutrition therapy. Use of cognitive motivational techniques, as well as programs of longer duration with greater simplicity and repetition, has been found to improve outcome.¹⁸⁹ Patients with diabetes of long duration, with poor metabolic control, and with major obstacles to lifestyle changes are most likely to benefit from intensive nutrition therapy.¹⁹⁰

A wide range of tools is available to facilitate meal planning for patients with diabetes.¹⁹¹ Which meal planning approach to use depends on the assessment of the individual patient's needs. *The Exchange Lists for Meal Planning*, long used to help patients select appropriate foods and portion sizes, may be too complex for some situations. A simplified version of the exchange system was found to be an effective meal planning tool during the DCCT. The carbohydrate counting method, which focuses on the nutrient with greatest influence on glycemic control, provides flexibility and can be implemented with varying degrees of complexity.¹³⁸

SUMMARY

The goals of nutritional management for diabetes mellitus can be achieved in a number of ways to meet patient needs. Provision of adequate energy intake to meet needs during periods of growth and development, pregnancy and lactation, and times of stress, injury, or illness are of primary importance. For patients with T2DM, reduction of total energy intake and an increase in physical activity consistent with the patient's physical capabilities should be recommended in order to reduce body fat, decrease insulin resistance, and improve glycemic and lipid control. Either a high-carbohydrate diet or a diet rich in *cis*-monounsaturated fats can be used as long as intake of dietary cholesterol and cholesterol-raising fats is limited. Intake of added sugars should be limited and carbohydrates rich in soluble fiber should be preferentially consumed. Recommendations for protein, vitamins, minerals, and fluids are similar to those for the nondiabetics. Emphasis should be on a healthy

lifestyle with a diet low in saturated and *trans*-unsaturated fats and rich in whole grains, fresh fruits, and vegetables. Referral to a qualified dietitian to assist the patient in establishing an individualized, realistic meal plan is essential. Because changing dietary habits is difficult, frequent follow-up will increase the likelihood of long-term positive outcomes of good glycemic control and prevention of short- and long-term complications.

Metabolic Implications of Exercise and Physical Fitness in Physiology and Diabetes

David H. Wasserman

Zhi-Qing Shi

Mladen Vranic

Exercise has long been considered beneficial in the treatment of diabetes mellitus. Its therapeutic usefulness was widely recognized by physicians in the nineteenth and early twentieth centuries. Following the discovery of insulin, Joslin and coworkers¹ and others recommended exercise as one of three basic principles in the management of diabetes. In the last two decades, many studies employing modern technology have investigated the relationship between fitness and metabolic control in diabetes. The rationale for the use of exercise as part of the treatment program is much clearer in type 2 diabetes mellitus (T2DM) than in type 1 diabetes mellitus (T1DM).² Thus, exercise is not currently regarded as a necessary management component for every diabetic individual, as it was in the past. Because physical exercise is related to improved quality of life, an assumption that has been made since classical Greek civilization, and has beneficial effects on the cardiovascular system, metabolic control should not be the only criterion by which to judge the benefits of a training program for diabetic patients.

A distinction must be made between the effects of acute exercise and those of physical training. For the body to meet the acute oxygen and fuel requirements of physical work and still minimize the deviations from homeostasis, metabolic, circulatory, and temperature-controlling adaptations are necessary. These short-lived regulations vary with the type, intensity, and duration of exercise; the muscles used; and a variety of environmental factors, such as physical condition and nutritional state. In contrast, the changes induced by physical training are long-term adaptations resulting from regularly performed exercise. In addition to improvements in work capacity, these chronic adaptations may also change the metabolic parameters during both rest and exercise. By nature, both local (muscular) and systemic effects of physical training are chronic and continue to be demonstrable for variable periods after physical exercise has stopped. Significant advances have been made in understanding the hormonal and substrate regulation of glucose fluxes during exercise in physiology and diabetes. This chapter highlights recent progress.

PHYSIOLOGY OF FUEL METABOLISM DURING EXERCISE

The increase in energy demand during exercise necessitates an accelerated flow of carbohydrate and fat from their storage sites to the energy-transducing machinery in the working muscle. To a

lesser extent, amino acids may be used as fuel, particularly when the availability of other substrates becomes limited. During the transition from rest to moderate-intensity exercise, the muscle shifts from using primarily free fatty acids (FFAs) to using a blend of FFAs, glucose, and muscle glycogen. During the early stages of exercise, muscle glycogen is the chief source of energy. With prolonged duration of exercise, the contributions of circulating glucose and, particularly, of FFAs, become increasingly important, as muscle glycogen gradually depletes. In addition, the origin of circulating glucose shifts from hepatic glycogenolysis to gluconeogenesis, as intrahepatic mechanisms channel a greater portion of the three-carbon molecules taken up by the liver into glucose.³ With increasing exercise intensity, the balance of substrate usage shifts to a greater oxidation of carbohydrates.⁴ Although the metabolic response to exercise will be influenced by such factors as nutritional state, age, type of exercise, and physical condition, the contribution of each specific substrate will always depend on work intensity and duration. Specific aspects of substrate metabolism can be defined in terms of three functional aims discussed as follows.

Preserving Glucose Homeostasis

Endogenous glucose production (GP) is so closely coupled to the exercise-induced increase in muscle glucose uptake that circulating glucose levels are generally not perturbed even though large increments in glucose usage may be present. Under certain conditions, however, blood glucose concentration may deviate from resting levels even in normal subjects. During prolonged exercise, gradually diminishing carbohydrate stores often result in a fall in blood glucose levels, whereas during heavy exercise, a rise in glycemia can ensue, as GP may exceed glucose metabolism.

Metabolizing the Most Efficient Substrate

Metabolic Efficiency

During high-intensity work when adenosine triphosphate (ATP) hydrolysis is accelerated and O₂ availability may be limited, carbohydrates are the preferred substrate. Generation of ATP from glucose oxidation in the cytoplasm occurs more rapidly than from fat oxidation in the mitochondria. Furthermore, since glucose carbon atoms are already partially oxidized compared to the highly

saturated carbon skeleton of fats, they require less oxygen for complete metabolism. Hence, when oxygen availability is limited, such as during heavy exercise, glucose is the most efficient fuel.

Storage Efficiency

Low-intensity exercise that can potentially be sustained for long intervals is characterized by a preference for fat oxidation. Under these circumstances, speed and efficiency of energy transduction become secondary to fuel storage efficiency. Differences in the degree of saturation of FFAs and glucose carbons predict that twice as much energy can be gained from the oxidation of triglycerides than an equal quantity of glycogen. In addition, while glycogen is stored with water, fats are immiscible with water and are stored in pure form. Hence, the economy of fat storage makes this fuel the most efficient for muscular activity of long duration.

Delaying Exhaustion

Fatigue during exercise that is not limited by the cardiopulmonary system is probably due to muscle glycogen depletion.⁵ To preserve muscle glycogen, a number of processes are accelerated. Glycerol, lactate, pyruvate, alanine, and other amino acids are channeled into the gluconeogenic pathway at an increased rate, thereby conserving carbon-based compounds. The contribution of FFA oxidation to total energy needs increases, thus sparing muscle glycogen. To a far lesser extent, branched-chain amino acid and ketone body oxidation will also increase. Prolonged exercise necessitates that extramuscular substrates be mobilized and made available to the working muscle with the goal of delaying muscle glycogen depletion. The rate at which these alternate substrates are used, however, must also preserve glucose homeostasis and allow for optimal metabolic efficiency.

REGULATION OF SUBSTRATE METABOLISM DURING EXERCISE

Control of the optimal substrate balance during exercise is achieved largely by the combined actions of insulin, glucagon, and the catecholamines (Fig. 27-1). In general, decreased insulin secretion and increased glucagon, catecholamine and cortisol secretion, among other hormones, characterize exercise. The signal for these hormonal and neural changes has been postulated to be increased afferent nerve activity originating at the working limb and splanchnic bed, a deficit in fuel availability, and/or neural feed-forward. In addition to hormonal factors, it is likely that other parameters, such as neural outflow originating in the central nervous system, blood flow shifts, and subtle changes in glycemia or the metabolic state, play a role in control of fuel metabolism during exercise.

Regulation of Endogenous Glucose Production

The interaction of increased glucagon and decreased insulin is the primary mechanism by which increases in hepatic glycogenolysis and gluconeogenesis are coordinated with the increase in glucose uptake during moderate-intensity exercise.⁶⁻⁸ For reasons that are discussed, it is possible that endogenous GP is regulated differently during high-intensity exercise.

Studies in humans using the pancreatic clamp technique show that simultaneously preventing the increase in glucagon and de-

FIGURE 27-1. Hormonal control and the interaction between the brain, liver, muscle, and fat cell in control of glucose homeostasis. It is indicated that glucagon/insulin interaction mainly controls hepatic glucose production, while epinephrine/insulin interaction controls peripheral glucose uptake, but the main role of the latter could be indirect through control of lipolysis in adipocytes (FFA-glucose cycle.)

crease in insulin leads to a fall in glucose ranging from about 25–50 mg/dL over the course of 1 hour.⁹⁻¹¹ This fall in blood glucose can occur despite a large compensatory increase in catecholamines. From these studies, it is apparent that changes in glucagon and/or insulin are essential to the maintenance of glucose homeostasis during exercise. These studies were extended by work in exercising dogs, and later in humans, that assessed the specific role of changes in insulin and glucagon.^{6,11} To selectively determine the role of the glucagon increment during moderate exercise in the dog, somatostatin was infused to suppress endogenous pancreatic hormone release, and insulin was replaced intraportally at basal rates at rest and with the normal fall in this hormone simulated during exercise.¹² Circulating glucose levels were clamped to prevent the confounding influence of hypoglycemic counterregulation. These studies showed that about 60% of the exercise-induced increment in GP is controlled by glucagon. This was consistent with findings in humans, showing that the rise in glucagon is necessary for glucose homeostasis during moderate exercise.¹¹ Studies in the dog also showed that the rise in glucagon is necessary for the full increment in both hepatic glycogenolysis and gluconeogenesis (Fig. 27-2).⁶ This stimulatory effect of glucagon on gluconeogenesis was due to an accelerated rate of gluconeogenic precursor extraction by the liver and enhanced channeling of precursor to glucose within the liver.

The role of the decrease in insulin level during moderate exercise was first ascertained in the dog by infusing insulin in the portal vein at a rate that prevented the fall in this hormone.¹³ Glucose levels were clamped throughout the exercise period in these studies. When the fall in insulin was selectively eliminated, the increase in hepatic GP was impaired due to an attenuation of hepatic glycogenolysis. The fall in insulin was calculated to control 55% of the increase in hepatic GP. The importance of the fall in insulin was subsequently confirmed by a study in human subjects showing that selectively preventing the exercise-induced fall in insulin using the pancreatic clamp technique led to a more expeditious fall in blood glucose.¹¹ In the dog, when the fall in insulin was prevented and glucose levels were not clamped, counterregulation (i.e., excessive catecholamine, glucagon, and cortisol increases) prevented

FIGURE 27-2. Role of the exercise-induced increase in glucagon in gluconeogenic regulation. Effect of exercise alone (shaded area), exercise with somatostatin plus simulated glucagon and insulin (solid line), and somatostatin plus basal glucagon and simulated insulin (dashed line) on (A) gluconeogenic conversion from alanine, (B) intrahepatic gluconeogenic efficiency from alanine, and (C) hepatic fractional alanine extraction. The exercise-induced increment in glucagon enhances gluconeogenesis by stimulating the gluconeogenic precursor extraction by the liver and channelling into glucose within the liver. Data are mean $\pm$ SE. (Reprinted with permission from Wasserman DH, Williams PE, Lacy DB, et al: *Exercise-induced fall in insulin and hepatic carbohydrate metabolism during muscular work*. Am J Physiol 1989; 256:E500.)

severe hypoglycemia by stimulating hepatic glycogenolysis and gluconeogenesis.⁶ Thus, while the fall in insulin plays an important physiologic role in the liver, effective counterregulation can partially compensate for the absence of the exercise-induced decrease in this hormone, and minimize the fall in glucose.

From the previous discussion, it is evident that coordinated and reciprocal changes in glucagon and insulin play important physiologic roles in accounting for virtually the entire increments in hepatic glycogenolysis and gluconeogenesis during moderate-intensity exercise. While changes in glucagon and insulin are individually very important, several lines of evidence indicate that it is the interaction of these changes that is the most critical. First, although changes in glucagon and insulin are both well correlated to the increase in endogenous GP, the ratio between glucagon and insulin exhibits the strongest correlation to this variable.^{7,8} Second, the glucagon increment controls about fourfold more of the increment in GP when insulin is allowed to fall, compared to when it is maintained at basal levels. Hence, during exercise, as is the case at rest, a fall in insulin sensitizes the liver to the effects of glucagon. Third, the fall in insulin has no effect on endogenous GP when biologically active glucagon levels are suppressed using somatostatin.⁶

It seems that epinephrine is unimportant in controlling endogenous GP during moderate-intensity exercise.⁶ Human subjects who were adrenalectomized for treatment of Cushing's disease or bilateral pheochromocytoma had a normal increase in GP during 60 minutes of moderate-intensity exercise, even though the changes in pancreatic hormone levels were similar to those in normal controls.¹⁴ Moreover, the increase in epinephrine plays only a minor

role in stimulating the increase in GP with moderate-intensity exercise in the dog and appears to occur only during the later stage of prolonged exercise (>120 minutes).⁶ Because of this, and the fact that it coincides with a diminished arterial lactate response, one can speculate that the effect of epinephrine is to facilitate gluconeogenic substrate mobilization from peripheral sites. This hypothesis is supported by the increased importance of epinephrine to glucoregulation in fasted rats, who are far more reliant on gluconeogenesis.¹⁵

A role for hepatic nerves in the stimulation of endogenous GP during exercise has been proposed based on two premises. First, an increase in hepatic glycogenolysis is evident during stimulation of the anterior hepatic nerve plexus, presumably caused by activation of sympathetic nerves.¹⁶ Second, the increase in endogenous GP that occurs with exercise is more rapid than changes in arterial glucagon, insulin, and epinephrine levels.¹⁶ Despite circumstantial evidence that seems to implicate the sympathetic nerves, a role during moderate exercise remains to be established. Combined α - and β -adrenergic blockade does not impair the increase in hepatic GP during moderate exercise in humans,¹⁷ implying that sympathetic drive is unimportant in this process. In addition, surgical hepatic denervation does not affect the increment in endogenous GP in rats,¹⁸ dogs,¹⁹ or humans.²⁰ It has recently been shown that sympathetic nerve blockade to the liver and adrenal medulla using local anesthesia of celiac ganglion in humans has no effect on the increase in hepatic GP.¹⁰

In humans, the hepatic response to high-intensity exercise and the regulation of this response are different from exercise of lesser intensity. The main difference in glucoregulation is that the ir

crease in GP is maximal, and no longer matches, but exceeds the rise in glucose utilization.^{21,22} This results in an increase in arterial glucose levels that extends into the postexercise state. In addition, insulin secretion is not suppressed and it is markedly increased in the postexercise period, facilitating recovery of muscle glycogen. Since a single bout of high-intensity exercise can only be sustained for a short interval, it is likely that the additional glucose released by the liver originates from liver glycogen. It has been hypothesized by Marliss and associates that during exercise of high intensity, there may be a shift in the control of GP away from the pancreatic hormones to the catecholamines.²² Most research indicates that catecholamines are unimportant in controlling hepatic GP during moderate-intensity exercise. However, during strenuous exercise, norepinephrine and epinephrine can increase by 10- to 20-fold, whereas the increase in the glucagon to insulin ratio is very small.²²

Using octreotide (a somatostatin analogue), the endogenous secretions of insulin, glucagon, and growth hormone were suppressed and replaced by infusion of the three hormones (islet and growth hormone clamp). Despite prevention of increases in growth hormone and glucagon and decrease of insulin, increments of glucose production were not affected. This strongly supports the notion that catecholamines are the primary regulators of glucose production during exercise in normal humans.²³ During moderate exercise glucose infusions inhibit GP, presumably by stimulating insulin release and suppressing glucagon secretion. In contrast, during strenuous exercise endogenous GP is partially preserved, despite glucose infusions or the postprandial state, supporting the role of catecholamines rather than the glucagon/insulin ratio.^{24,25} An additional argument is that epinephrine and norepinephrine infusions during moderate exercise can substantially increase GP, thus mimicking the effects of strenuous exercise.²⁶ Nevertheless, human studies that have attempted directly to assess the role of catecholamines in stimulating hepatic GP during heavy exercise (> 80% maximum O₂ uptake) have been negative.¹⁰ A recent study in dogs showed that complete blockade of α - and β -adrenergic receptors, specifically at the liver, had no effect on high-intensity exercise that resulted in a twofold increase in hepatic norepinephrine spillover.²⁷ However, the exercise was much less intense in these human and dog studies than in those reported by Marliss.²² It remains to be explored whether nonadrenergic or noncholinergic mechanisms could also be involved.

The question of whether the GP increment in humans during strenuous exercise is regulated by α - and β -catecholamine receptors was studied by Marliss's group in healthy subjects in whom a complete β -blockade was achieved during exercise at 87% V_{max}.²⁸ The GP increment was not suppressed by β -blockade, but actually rose twofold more than controls, attributed to an excessive and "unmasked" α -adrenergic effect that can also stimulate hepatic GP.²⁹ It is unknown whether GP might be increased in strenuous exercise through an additive effect of both catecholamine receptors, although this is feasible since α -effects can increase glycogenolysis through Ca²⁺ and protein kinase C, whereas β -effects work through cAMP and protein kinase A signaling mechanisms. Blockade of α -receptors also does not decrease GP, suggesting that enhanced β -effects maintain GP unchanged.²⁹

Regulation of Fat Metabolism

Moderate exercise is typically associated with an approximate 10-fold increase in fat oxidation due to increased energy expendi-

ture coupled with greater FFA availability. Lipolysis, assessed by the increase in arterial glycerol concentration and isotopic techniques, increases with the onset of moderate exercise.³⁰ Arterial FFA levels increase gradually. The slower time course for the rise in plasma FFA levels reflects an increase in clearance of this fuel by the working muscle.³⁰ The increase in FFA availability is largely due to an increase in lipolysis from adipose tissue triglycerides. In addition, the percentage of released fatty acids that are reesterified is decreased by 50%,³⁰ presumably because of alterations in blood flow that facilitate the delivery of fatty acids from adipose tissue to working muscles.

FFA release from adipose tissue is regulated primarily by the actions of insulin and the catecholamines. When the exercise-induced fall in insulin is prevented in dogs⁶ and humans,¹¹ the increase in FFA levels is prevented. In the dog, this effect is accompanied by an attenuated rise in arterial glycerol. Adipocytes taken from human subjects following exercise have an increased lipolytic responsiveness to catecholamines, which is mediated through β -adrenergic mechanisms and occurs without an increase in the binding of the β -receptor-specific catecholamine, [¹²⁵I]-cyanopindolol.³¹

In contrast to the role of FFA mobilization from adipose tissue during moderate-intensity exercise, its role during high-intensity exercise is considerably less important. Despite the increased adrenergic drive that is present during high-intensity work, the arterial FFA level in plasma decreases. A diminished lipolytic response and increased rate of reesterification to the diminished increase in FFA mobilization could lead to a decrease in FFA availability. Stimulation of adipocytes' β -adrenergic receptors is negatively coupled to adenylate cyclase and decreases lipolysis. The decrease in FFA mobilization during high-intensity exercise may be due to stimulation of β -adrenergic receptors by the high epinephrine concentrations that occur under these conditions.³² Increased reesterification of FFAs due to excessive lactate levels during high-intensity exercise has been proposed as a possible reason for the decrease in FFA availability. This is consistent with the observation that blood glycerol levels may still rise during heavy exercise even when FFAs are not increased. It is also possible that increased blood glycerol levels are due to release from triglycerides within the working muscle. FFAs that are liberated in the process are oxidized locally, within the muscle.

With regard to the possible role of intramuscular triglycerides stores during exercise, there is a large body of evidence suggesting that they may represent an important metabolic substrate.³³ Estimates of the oxidation of intramuscular fat stores that were calculated indirectly using whole-body isotopic methods suggest that intramuscular fats provide more than 50% of the total fat oxidized during exercise³⁴ and muscle contraction.³⁵ Results obtained using muscle biopsies or arteriovenous differences, however, generally cannot account for such a large contribution of muscle fat store during exercise.³⁶

The increase in ketogenesis that occurs with prolonged exercise seems to be in large part due to the increased lipolytic rate and consequent increase in FFA delivery to the liver. When the increase in FFA levels is abolished either by preventing the fall in insulin⁶ or by β -blockade,¹⁷ ketone body levels do not rise. In addition to hepatic FFA delivery, the exercise-induced rise in glucagon appears to be necessary for the full increase in ketogenesis.⁶ The ketogenic effect of glucagon that occurs without altering net hepatic FFA uptake indicates that glucagon stimulates this process at a site within the liver.

Control of Muscle Glycogenolysis

Muscle glycogen is an important local fuel during the early stages of exercise. With prolonged duration of exercise, glycogen stores decline in working muscle and glycogenolysis is stimulated in inactive muscle fibers.⁶ In these muscles, glycogen is metabolized to lactate, where it is released and then delivered to the liver to be used in the gluconeogenic pathway. Increasing work intensities accelerate the rate of glycogen breakdown in contracting muscle. Glycogen breakdown is regulated by the rate-limiting enzyme glycogen phosphorylase. Phosphorylase is phosphorylated by phosphorylase kinase, creating the active form of the enzyme, phosphorylase *a*. The enzyme is dephosphorylated to its inactive form, phosphorylase *b*, by phosphorylase phosphatase. It is interesting, however, that although muscle glycogenolysis increases with increasing workload, there is no increase in phosphorylase transformation to its active form.³⁷ This suggests that allosteric regulators, such as AMP and inorganic phosphate, allow for glycogen phosphorylase to be matched to energy demands. Studies using β -adrenergic blockade indicate that catecholamines play a major role in mobilization of muscle glycogen during exercise.⁶ Studies in the isolated rat hindlimb indicate that in addition to epinephrine, contraction *per se* can stimulate muscle glycogenolysis even in the complete absence of catecholamines.³⁸ Intracellular cAMP levels mediate the activation of phosphorylase *a* and the stimulation of muscle glycogenolysis by catecholamines. It appears that contraction causes the events by releasing calcium from the muscle sarcoplasmic reticulum.

Exercise-Induced Muscle Glucose Uptake

Muscle glucose uptake is closely regulated by hormonal and non-hormonal mechanisms (Fig. 27-3). Kinetic analyses of glucose uptake conducted *in vivo*⁶ and *in vitro*³⁹⁻⁴¹ generally indicate that the maximal velocity ($V_{\max}$) for this process is increased by exercise without affecting the Michaelis-Menten constant (K_m) (Fig. 27-4). The K_m for glucose oxidation by the working limb is the same as for glucose uptake, implying that both processes are controlled at the same step.⁶ Stimulation of muscle glucose uptake by exercise depends, as it does for insulin and other regulators of glucose uptake, on the muscle interstitial to intracellular glucose gradient (transport gradient) and the permeability of the sarcolemma to glucose. Exercise increases muscle glucose transport dramatically while maintaining the transport gradient. Both effects of exercise are obviously critical for muscle glucose uptake and are described below.

Glucose Transport Gradient

The glucose transport gradient is determined by the rate that glucose is delivered to the muscle and the rate that free glucose transported across the sarcolemma is cleared once it is inside the cell. It is important to recognize that muscle interstitial glucose would fall precipitously and the glucose transport gradient would be insufficient to sustain glucose uptake if it were not for a marked increase in muscle blood flow that replenishes the interstitial glucose as it enters the working muscle. The increase in muscle blood flow is due to an increase in cardiac output and local vasodilation of the arterioles to the working muscle and is directly related to work rate.⁴² The capillary endothelium is permeable to glucose and is not a limiting factor in supplying glucose to the working muscle. The diffusion distance to the sarcolemma, once glucose exits the

FIGURE 27-3. Pathways regulating glucose transport in skeletal muscle during exercise. Pathways of glycolysis, glycogenolysis, lipolysis, oxidation, and oxidative phosphorylation are shown in outline. The circle numbers refer to the following sequence of metabolic events: (1) the release of acetylcholine from motor neurons, (2) the activation of muscle contractile activity, (3) the increase in ATP turnover leading to a decrease in the molar ratio of ATP/ADP $\times$ Pi, and (4) the increased mitochondrial oxidation of reduced coenzymes. This leads to an increased oxidation of acetyl CoA deriving from glucose or fatty acids. A decrease in the levels of glucose-6-phosphate might enhance extracellular glucose uptake mediated via cytochalosin β -inhibitable glucose transporters. Thus, in the absence of extracellular insulin, contraction triggers extracellular glucose uptake via insulin-independent pathways. Note that there are at least three sources of endogenous FFAs in muscle: plasma FFAs, plasma triglycerides associated with lipoproteins (LPL, TG), and endogenous triglycerides. The thick arrows delineating the pathways of FFA oxidation emphasize the fact that fatty acids are the principal substrates oxidized by muscles at rest and during prolonged exercise. If FFAs are present in excess (such as in diabetes), they retro-inhibit glucose oxidation. Likewise, if fatty acid oxidation is inhibited (by drugs such as methylpalmitoxirate or by anaerobic conditions), then glucose oxidation is increased. Although the detailed biochemical mechanism of the FFA-glucose cycle remains to be determined, it is hypothesized that this cycle is more important for the regulation of glucose metabolism in red oxidative muscle than in white glycolytic muscles. (This scheme is kindly provided by Dr. L. Bukowiecki of Laval University School of Medicine, Quebec.)

capillary, however, may be critical. Fast-twitch fibers have a low capillary density and are poorly perfused; therefore, the diffusion distance is greater in fast-twitch than slow-twitch fibers that are well perfused. One would predict that at equivalent rates of muscle glucose transport, glucose concentration at the sarcolemma of fast-twitch muscle, and therefore the glucose transport gradient, would be lower than it is in slow-twitch fibers. It may, in part, be for this reason that fast-twitch muscle fibers are not able to sustain rates of glucose uptake as high as slow-twitch fibers.⁴³

The importance of glucose supply to working muscle is supported by several observations. First, there is a close correlation of

FIGURE 27-4. Dose-response relationship between glucose concentration and glucose transport in apirochlearis muscle at rest, during contractions (48 twitches/min), incubated in the presence and absence of insulin (10 mU/mL). Also shown are the rates of nonfacilitated glucose diffusion obtained by incubating the muscle in the presence of cytochalasin 8 (50 μ M). Note that both insulin and contractile activity increase the apparent V_{max} without significantly changing the apparent K_m (5–8 mmol). (Reprinted with permission from Neshor R, Korl IE, Kipris KM. Dissociation of the effect(s) of insulin and contraction on glucose transport in rat epitrochlearis muscle. *Am J. Physiol.* 1985;249:C226)

muscle blood flow to glucose uptake by the working human limb.^{44,45} Second, an increase in perfusion of the isolated rat hindlimb is necessary for the full contraction-induced glucose uptake in this preparation.⁴⁶ Finally, increasing blood glucose supply by creating hyperglycemia with an intravenous glucose infusion resulted in a marked increase in limb glucose uptake in the exercising dog, even when hyperinsulinemia was prevented using somatostatin.⁶ The exercise-induced increase in glucose delivery is so effective at maintaining interstitial glucose that an increase in muscle fractional glucose extraction is not required for the increase in muscle glucose uptake.⁶

The muscle intracellular free glucose concentration determines the “downward” slope of the glucose transport gradient. As a consequence, the ability to metabolize glucose critically determines the glucose flux across the sarcolemma. The first step in glucose metabolism is phosphorylation by hexokinase II. In addition to maintaining intracellular glucose concentration low, glucose phos-

phorylation is important because the product, G6P, cannot exit the cell and is the substrate for subsequent glucose metabolism. Although glucose uptake is probably rate-limited by glucose transport at rest, there is evidence that glucose phosphorylation becomes limiting if glucose transport is stimulated to a critically high level of G6P, which inhibits hexokinase II.^{47–50} Not only are muscle glucose delivery and transport elevated during exercise, but glycogenolysis is high, flooding the G6P pool. The consequence is a greater role for glucose phosphorylation in control of muscle glucose uptake during exercise.^{51,52} Figure 27-5 illustrates how overexpression of hexokinase II improves the ability to consume the 2-deoxyglucose in mice and how a glycogen-depleting fast can enhance the uptake of this glucose analog even further, presumably by reducing the size of the G6P pool.⁵¹ Conversely, the importance of muscle glycogenolysis as a factor controlling muscle glucose uptake is reflected by the high G6P concentration and attenuated increase in contraction-stimulated glucose transport in perfused rat hindlimb muscle with a high initial glycogen mass.⁵³ This concept is further supported by results from human subjects’ cycling after a single leg has been glycogen-depleted by prior exercise.⁵⁴ The limb with glycogen-depleted muscle has a higher net rate of glucose uptake and lower muscle G6P levels than the contralateral control limb.

FIGURE 27-5. [$2\text{-}^3\text{H}$]DGP content in soleus, gastrocnemius (gastroc), vastus lateralis (vastus), and diaphragm normalized to brain [$2\text{-}^3\text{H}$]DGP content after a 30-minute sedentary period (A), or a 30-minute treadmill exercise period in 5-hour fasted (B) or 18-hour fasted (C) mice overexpressing hexokinase II or wild-type litter mates. Data shown are mean $\pm$ SE; $n = 8$ and 6 for sedentary wild-type and transgenic, $n = 8$ and 12 for 5-hour fasted exercise wild-type and transgenic, and $n = 6$ and 6 for 18-hour fasted wild-type and transgenic. *Indicates significantly greater [$2\text{-}^3\text{H}$]DGP content in transgenic than wildtype ($p < 0.05\text{--}0.005$).

In contrast to the extensive work assessing exercise and glucose transport, very little is known regarding the effects of exercise on hexokinase II and glucose phosphorylation. There have been no positive allosteric regulators of hexokinase II identified. Therefore, enzyme compartmentation and mass are likely to be key regulatory factors. It has been shown in this regard that prolonged, moderate exercise to exhaustion in the rat results in a small increase in the percentage of muscle hexokinase activity associated with mitochondria.⁵⁵ Consistent with this is the observation that chronic, low-frequency stimulation can lead to a redistribution of muscle hexokinase activity so that more of the enzyme is in an insoluble fraction.⁵⁶ In marked contrast, however, is the demonstration that the percentage of hexokinase activity bound to mitochondria fell by about 80% in skeletal muscles of horses run to exhaustion at 100% of their maximum oxygen uptake.⁵⁷ Based on the latter results, it was hypothesized that the reduction in bound hexokinase during high-intensity exercise was a result of the increase in muscle G6P that induced the release of hexokinase from mitochondria.

Acute exercise has been shown to stimulate skeletal muscle hexokinase II gene transcription.⁵⁸ Interestingly, increases in gene transcription,^{58,59} mRNA,^{60–62} and protein synthesis^{61,62} with exercise or electrical stimulation of the nerve to a muscle precede and are larger for hexokinase II than GLUT-4. The increase in hexokinase activity lags behind the increase in hexokinase II mRNA^{60,61} and may, therefore, be more significant to the persistent increase in insulin action following exercise or the adaptations that occur with training.

Because G6P is such a potent inhibitor of hexokinase II activity, the capacity to metabolize it is necessary for the accelerated rate of glucose phosphorylation required by the working muscle. In contrast to insulin-stimulated glucose utilization where glycogen formation is the primary fate of G6P, the muscle G6P formed during exercise is, at least in a net sense, metabolized entirely glycolytically.^{6,63–65} Consequently, the capacity for muscle glycolysis and glucose oxidation is a determinant of muscle G6P concentration and, as a result, glucose uptake.

Sarcolemma Glucose Transport

Exercise is associated with an increase in glucose transporter number in sarcolemma^{40,66–68} and specifically at T tubules⁶⁶ isolated from rat skeletal muscle. It has been proposed that the intrinsic activity of the glucose transporter is also increased in sarcolemma from exercised rats.⁶⁷ The finding of increased intrinsic activity, however, is probably a consequence of measuring glucose transporters that are both accessible and inaccessible to extracellular glucose.⁶⁹ Studies using a photo-label that identifies only GLUT-4 accessible to extracellular glucose has shown that the exercise-induced increase in glucose transport can be explained entirely by an increase in sarcolemma GLUT-4 number.^{70,71} The increased transporter number is due specifically to an increase in plasma membrane GLUT-4, as plasma membrane GLUT-1, the other isoform found in muscle, is unaffected by exercise.^{72,73} The increase in plasma membrane GLUT-4 in response to exercise is, like that due to insulin stimulation, a result of an increase in translocation from an intracellular pool.

The studies just described show that an increase in glucose transport is clearly important to muscle glucose uptake and metabolism during exercise and that GLUT-4 is the protein responsible for the increase in glucose transport. The importance of other regulatory factors, however, is clearly exemplified during submaximal

work by the negative correlation between rate of whole body glucose utilization and muscle total GLUT-4 in humans.⁷⁴ This seemingly paradoxical relationship can exist since muscles rich GLUT-4 also have metabolic properties that make them better able to derive energy from fats and therefore require less glucose. The higher muscle total GLUT-4 levels better enable an individual to meet the challenges of maximal exercise. However, “glucose sparing” mechanisms take precedence at submaximal work rate. As a consequence, there is less muscle glucose uptake even though the key glucose transport protein is more abundant.

Important advances in how contraction triggers the increases in GLUT-4 translocation and muscle glucose uptake have been made over the last several years. As discussed as follows, the mechanism for the increase is clearly different from that of insulin. A hypothesis that is gaining growing support is that the exercise-induced increase in muscle AMP stimulates AMP kinase, which then causes an increase in muscle glucose uptake.⁷⁵ This is supported by the demonstration that the pharmacological agent 5-aminoimidazole 4-carboxamide 1- β -D-ribofuranoside (AICAR) activates AMP kinase and has a stimulatory effect to increase uptake in perfused rat hindlimb⁷⁶ and isolated muscle.⁷⁷ As is the case with muscle contraction, AICAR appears to activate muscle glucose uptake by GLUT-4 translocation.⁷⁷

In addition to the stimulation of AMP kinase by AMP, Ca^{2+} and nitric oxide (NO) have also been proposed to mediate the exercise-induced increase in muscle glucose uptake. Because increased cytoplasmic Ca^{2+} is an essential part of the contraction process and is involved in many aspects of intracellular metabolic regulation, it has been proposed that deficient depancreatized dogs is increased by only 25–50% of the response seen when insulin is replaced.⁸² The reason for the difference between studies in isolated muscle and studies in the whole organism is that insulin acts indirectly to maintain a metabolic state that is conducive to exercise-stimulated glucose uptake *in vivo*. This is exemplified by studies that show that if characteristics of chronic insulin deficiency (e.g., enhanced nonesterified fatty acid levels, elevated catecholamines) are minimized, insulin-independent mechanisms are sufficient to stimulate glucose utilization *in vivo*. Consistent with this hypothesis, β -adrenergic blockade during exercise suppresses FFA levels and increases the impaired rise in glucose utilization present in diabetes.^{83,84} Somatostatin has been used to create an acute insulin deficiency in dogs, since in combined insulin and glucagon deficiency, a time period exists when the animal is not hyperglycemic or hyperlipidemic.⁶⁴ Under these conditions, the contribution of insulin-independent mechanisms to the exercise-induced increase in whole-body glucose utilization, limb glucose uptake, and limb glucose oxidation in dogs ranges from 50–70%. The contribution of insulin-independent mechanisms has also been estimated in humans by the extrapolation of data obtained in humans during insulin clamps to a theoretical insulin value of zero.⁸⁵ These estimates suggest that virtually all of the exercise-induced increases in glucose uptake and carbohydrate oxidation are insulin-independent. Taken together, *in vivo* and *in vitro* experiments consistently show that muscular work is a potent stimulus for insulin-independent glucose uptake and metabolism when severe insulin deficiency is not present.

The cell-signaling pathway of contraction-stimulated glucose transport is distinct from that for insulin-stimulated glucose transport. Although the increase in plasma membrane transporters in response to both insulin and exercise results from an increase in translocation of GLUT-4, these stimuli recruit GLUT-4 from differ-

ent intracellular pools.^{66,78,86} Evidence that cell signaling for glucose uptake is different for exercise and insulin is supported by the demonstration that these two stimuli are functionally additive,^{70,71} as are the corresponding increases in GLUT-4 translocation.^{70,71,87} Moreover, electric stimulation of rat skeletal muscle *in situ* does not lead to the phosphorylation of proteins involved in insulin signaling, such as insulin receptor substrate-1,⁸⁸ PI 3-kinase,⁸⁸ Akt2 kinase,⁸⁹ Akt3 kinase,⁸⁹ and p70^{s6k}.⁹⁰ In addition, wortmannin, an inhibitor of PI 3-kinase, eliminates insulin-stimulated glucose transport but does not impair^{71,91,92} contraction-stimulated glucose transport in isolated rat skeletal muscle.

In further support of unique mechanisms for insulin- and contraction-stimulated glucose transport is the demonstration that physiologic and pathologic factors can affect them differently. High-fat feeding⁹³ and maturation⁹⁴ both decrease insulin-stimulated skeletal muscle glucose uptake, without diminishing contraction-stimulated glucose uptake. Furthermore, muscles isolated from the obese Zucker rat have diminished glucose transport and sarcolemma GLUT-4 with insulin stimulation, but respond normally to contraction.^{43,70} The differential effects of these conditions on insulin emphasize that the insulin signaling pathway is different from that stimulated by contraction.

Modulation of Glucose Uptake by the Working Muscle by the Internal Milieu

The preceding discussion describes the basic mechanisms that control muscle glucose uptake during exercise. Hormones and substrates in the circulation can further regulate this response. The following are some of the means by which humoral factors influence the exercise response.

Insulin Sensitivity of the Working Muscle

In addition to the increase in insulin-independent glucose utilization during exercise, insulin sensitivity is also increased.^{6,39,44,95,96} Studies conducted in humans show that exercise and insulin stimulate glucose utilization and carbohydrate oxidation synergistically over a range of insulin doses by affecting both the K_m of insulin and V_{max} of these pathways.⁸⁵ The effects of this increase in insulin action are probably most important in the postprandial state and in the intensively treated diabetic state when insulin levels can be higher than those that normally accompany exercise. There is, nevertheless, an increased sensitivity of glucose uptake to the subbasal insulin levels present during exercise in the postabsorptive state.⁹⁷ Exercise also has a potent effect on the intracellular pathway for insulin-stimulated muscle glucose metabolism. The primary route of insulin-mediated glucose metabolism at rest⁹⁸ and in the postexercise state⁹⁹ is nonoxidative metabolism. Acute exercise, however, shifts the route of insulin-stimulated glucose disposal so that all the glucose consumed by the muscle is oxidized.⁸⁵

Several mechanisms have been proposed to explain how exercise enhances insulin action. These mechanisms can be classified as those that exert their effect on muscle indirectly through the hormone's action at another site and those that act directly at the muscle. The increased blood flow to the working muscle increases the exposure of this tissue to circulating insulin and may reflect one mechanism for increasing insulin action on muscle indirectly.^{44,100} The relationship between the exercise-induced increase in muscle blood flow and the increase in insulin sensitivity has been illus-

trated by studies in the perfused rat hindlimb.⁴⁶ Increasing the perfusate flow augmented the effect of insulin on glucose uptake when the hindlimb muscles were stimulated to contract. If trans-endothelial insulin transport determines the kinetics of insulin action, as discussed elsewhere,¹⁰¹ then the hemodynamic adjustments result in increased capillary surface area in the working muscle, which may enhance insulin action by increasing insulin transport across the endothelium.

Exercise may also increase insulin-stimulated glucose utilization by a mechanism secondary to insulin's suppressive effect on nonesterified FFA availability. The absolute magnitude of the insulin-induced suppression of plasma FFA levels and fat oxidation is greater during exercise. This may represent a second indirect mechanism by which exercise increases insulin action. The K_m 's for total carbohydrate and fat oxidation occur at similar insulin levels during exercise, suggesting that the greater stimulation of carbohydrate oxidation may be an essential response to a primary suppression of lipolysis.⁸⁵ The interaction of circulating FFA concentrations and muscle glucose uptake during exercise is described in a subsequent section.

Studies in humans¹⁰² and rats^{102–105} generally indicate that insulin binding affinity to skeletal muscle is unaffected by acute moderate exercise. Since insulin binding affinity is unaltered, it has been concluded that a step distal to binding must be altered.¹⁰⁵ It has been proposed that a postreceptor modification may be linked to the glycogen-depleting effect of exercise. One recent study showed that the ability of muscle contraction to enhance insulin-stimulated glucose uptake and transport in the perfused rat hindquarter was eliminated by adenosine receptor blockade.⁹⁶ Adenosine receptor blockade had no effect during contraction in the absence of insulin. This suggests that the increased adenosine production that occurs in response to muscular work¹⁰⁶ plays a role in facilitating insulin action.

Effect of Circulating FFA Concentrations on the Working Muscle

Insulin-stimulated muscle glucose uptake can be attenuated by elevated circulating FFAs concentrations.^{107,108} A similar link between elevated FFA and depressed muscle glucose uptake during exercise has also been shown in studies using arteriovenous difference methods across the working human leg.¹⁰⁹ A twofold increase in FFA concentrations elicited by infusion of a lipid emulsion reduced leg glucose uptake from 30–60% during 60 minutes of knee extension in human subjects. This finding was supported by a study in the exercising dog that showed that reducing FFA levels by about 70% by suppressing lipolysis with nicotinic acid leads to an increase in whole-body glucose utilization and an approximately 70% increase in limb glucose oxidation.¹¹⁰ The mechanism for the high FFA-induced impairment in glucose uptake by working muscle may be different than the one originally proposed by Randle and coworkers.¹¹¹ Randle and colleagues proposed that fats impaired muscle glucose uptake by metabolic feedback resulting from accumulation of metabolic intermediates involved in fat oxidation. During lipid infusion, glucose uptake by the working human limb was impaired during lipid infusion even though G6P was not increased.¹⁰⁹ Moreover, increasing fat availability to working human muscle by diet, triglyceride infusion¹¹² does not decrease pyruvate dehydrogenase activity or lead to an accumulation of citrate or acetyl-CoA in muscle biopsies. Taken together, these studies suggest that an increase in fat availability impairs glucose uptake in working muscle by a different mechanism. Since the in-

hibition of glucose uptake does not necessitate the buildup of G6P or metabolic intermediates downstream from this metabolite, the conclusion may be that elevated FFA levels inhibit muscle glucose uptake at either the glucose transport or glucose phosphorylation step. These findings are in agreement with studies that show that high FFA levels decrease whole-body glucose utilization during hyperinsulinemic euglycemic clamps without increasing G6P in resting human subjects.^{113,114}

Effect of Decreased Oxygen Availability on the Working Muscle

Excessive increments in muscle glucose uptake occur when O₂ availability is limited, such as exercise under anemic conditions,¹¹⁵ when breathing a hypoxic gas mixture,¹¹⁶ or at high altitude.¹¹⁷ This occurs even when energy expenditure is no greater. Moreover, elevated rates of glucose uptake occur under these circumstances even though insulin levels are no higher and catecholamines, which may be antagonistic to glucose uptake, are greater. These findings are consistent with studies, conducted in perfused¹¹⁸ rat skeletal muscle, that show the close relationship of hypoxia, and the consequent metabolic state, to glucose uptake. The mechanism that links muscle metabolism to glucose uptake remains to be identified. It is noteworthy, however, that hypoxia-stimulated and contraction-stimulated skeletal muscle glucose transport share common features and may, in fact, involve the same signaling steps.

Effect of Adrenergic Stimulation on the Working Muscle

Glucose uptake by working muscle may also be impaired when adrenergic stimulation is excessive. Epinephrine infusion inhibits tracer-determined whole-body glucose clearance in the exercising dog,¹¹⁹ and a local infusion of epinephrine into an artery of one leg led to a reduction in leg glucose uptake compared to the contralateral leg during cycle exercise in humans.¹²⁰ Conversely, β -adrenergic receptor blockade increased whole-body glucose utilization^{117,121} and oxidation^{117,121} and leg glucose uptake¹¹⁷ in humans during cycling. One mechanism for the inhibitory effect of the catecholamines on muscle glucose uptake is the inhibition of hexokinase due to the increase in muscle G6P resulting from stimulation of glycogenolysis. The potential importance of this mechanism is illustrated by the 50% reduction in G6P that occurred during β -adrenergic receptor blockade in the working muscle of humans.¹²² In addition, metabolic effects due to catecholamine-stimulated lipolysis (as discussed) may also be a factor.¹¹¹

Effect of Carbohydrate Ingestion on Glucose Metabolism During Exercise

An important factor limiting exercise endurance is the depletion of endogenous carbohydrate stores. Many studies have indicated that glucose feeding during exercise was shown to improve exercise endurance or allow resumption of exercise after exhaustion. The principal underlying mechanism for this improvement is probably related to increased glucose availability to the working muscle. The prevention of neuroglycopenia is not likely to be the mechanism by which carbohydrate ingestion prevents fatigue since severe hypoglycemia is not necessarily present at exhaustion. During exercise, moderate levels of hypoglycemia (consequent to liver glycogen depletion) induce marked glucagon and catecholamine responses,

further increasing the stimuli for muscle and liver glycogen breakdown and expediting glycogen depletion. This cycle can be broken by carbohydrate ingestion. The amount, form, and timing of an oral carbohydrate load, along with the duration and intensity of exercise, will determine how effectively glucose enters the bloodstream, thus becoming available to the working muscle.

Multiple factors determine the metabolic availability of ingested carbohydrates. Two components are involved in the absorption of an oral carbohydrate load: transit time through the small intestine and intestinal sugar absorption. Transit time through the intestine is determined by gastric emptying and intestinal motility. Gastric emptying is influenced by the volume, osmolality, temperature, energy content, acidity, and presence of specific nutrients in the ingested meal. Of these, volume is the most potent activator of gastric emptying, whereas high carbohydrate concentrations slow the emptying rate. The question of whether moderate exercise changes gastric emptying is controversial. The discrepant results may pertain to methodology or study design. Exercise at greater than 70% of the maximum oxygen uptake has consistently been shown to slow gastric emptying.¹²³ It is clear that specific conditions that accompany intense exercise, such as dehydration and sympathetic nervous activity, may inhibit gastric emptying. Generally, experiments show that small intestine transit time is increased by exercise.

The direct effect of exercise on intestinal absorption has received very little attention. Moderate-intensity cycling (around 45% maximum oxygen uptake) has been shown to lead to a reduction in water and electrolyte absorption as determined using jejunal perfusion.¹²⁴ This finding is consistent with other work that showed that the vascular appearance of ingested deuterium oxide was reduced by high-intensity exercise.¹²⁵ High intensity exercise reduces splanchnic blood flow in humans by as much as 70% during high-intensity exercise.¹²⁶ This hemodynamic change may, therefore, impair the absorption of ingested glucose.

The metabolic availability of ingested carbohydrates has been assessed in numerous studies by spiking the oral load with sugar labeled with isotopic carbon and measuring the appearance of the isotope in expired CO₂. Initial studies were done using ¹⁴C-glucose to trace the oxidation rate of ingested glucose. However, these studies underestimated exogenous glucose oxidation due to technical problems that arise from the extensive interval required for the H₁₄CO₃ to equilibrate with the endogenous HCO₃ stores. In subsequent years, the metabolic availability of ingested glucose was measured using ¹³C-labeled sugars. Use of this label, on the other hand, has given rise to overestimates due to the presence of a naturally occurring ¹³C label. Since the ¹³C enrichment of glucose is greater than fats, an increased contribution of carbohydrate to total fuel oxidation (as is seen during exercise) will result in an increase in ¹³CO₂ production. Early work that did not consider the contribution of endogenous carbohydrates overestimated the rate of ingested carbohydrate oxidation. More recent work determined that the exact metabolic availability of ingested carbohydrate depends on many factors related to the composition and quantity of the substrate load. In addition, exercise parameters (i.e., work intensity, duration, modality) will also be an important determinant of how readily ingested glucose will be made available. As a consequence, it is difficult to ascribe an exact efficiency for metabolism of ingested glucose. A reasonable estimate might be that approximately 40% of a 50-g oral glucose load ingested at the start of moderate-intensity exercise is metabolized during the first hour.¹²⁷

During light work rates, there is probably little difficulty in delivering adequate amounts of ingested glucose to the working muscle. As glucose oxidation by the working muscle increases at higher work rates, it may no longer be possible to absorb adequate amounts of ingested glucose from the gastrointestinal tract. Thus, what limits ingested oxidation may shift at different work intensities—low muscle demand limits glucose oxidation at light work rates, whereas absorption from the gastrointestinal tract limits it at high work rates. One study showed that as exercise intensity increased from 22 to 51% of the maximum oxygen uptake, the oxidation of ingested glucose (100 g) increased proportionally.¹²⁸ With further increases in work rate, total carbohydrate oxidation continued to rise, but the oxidation of ingested glucose increased no further, suggesting that the rate at which glucose is made available from the gastrointestinal tract had become limiting.

Several approaches have been used to increase the rate of ingested carbohydrate availability to the working muscle. Some of these are described as follows:

1. *Increasing the mass of ingested carbohydrates.* One approach for increasing the amount of carbohydrate that is absorbed is simply to increase the mass of ingested glucose. This is an effective approach even though the fraction of the ingested glucose that is made available for metabolism is actually decreased with a greater oral glucose load. In one study, a 400% increase in the carbohydrate ingested mass induced only a 25% increase in exogenous glucose oxidation; as a result, a large increase (from 45% to 81%) of ingested carbohydrates remained in the gastrointestinal tract.¹²⁹ The decreased percentage of ingested glucose oxidized when larger quantities of ingested glucose are consumed suggests one or more steps involved in the intestinal absorption or delivery of glucose to the working muscle have become saturated.
2. *Ingestion of different carbohydrate types.* Sucrose ingestion has been used as a source of substrate during exercise, with the goal of decreasing ingestant osmolarity with similar effectiveness as ingested glucose.¹³⁰ This is not surprising because the hydrolysis of this sugar leads to the entry of glucose into the circulation. More sugar can be made metabolically available by using different sugar types. A greater percentage of ingested sugar is oxidized during exercise if 50 g of glucose and 50 g of fructose are ingested than if 100 g of glucose alone is consumed.¹²⁷ Studies examining the effectiveness of fructose¹²⁷ alone suggest that it is less effective than glucose at sparing endogenous carbohydrate stores. Due to a smaller insulin response with nonglucose sugars, FFA levels are higher than following glucose ingestion, but this does not seem to improve exercise tolerance.¹³⁰
3. *Timing of ingested glucose.* The beneficial effect of carbohydrate ingestion on exercise endurance seems to be equal whether the meal is fed prior to, at the onset of, or during exercise, provided that the onset of exercise does not coincide with the postingestion insulin peak (about 45 minutes after ingestion)¹³¹ and signs of fatigue are not already present.¹³²

At least two important endocrine changes accompany the increase in glucose availability. The exercise-induced fall in insulin and rise in glucagon are attenuated or eliminated altogether.¹³³ The absence of the fall in insulin will attenuate the increases in lipolysis and GP,^{6,11} whereas a reduction in glucagon will reduce the latter.^{6,11} The suppression of lipolysis will result in a reduction in

circulating FFA levels, which has been shown to stimulate tracer-determined glucose utilization and glucose oxidation by the working limb.¹¹⁰ Although insulin acts to suppress net muscle glycogen breakdown, multiple signals are present in the working muscle and these counterbalance the antiglycogenolytic effects of insulin more often than not.

Because of the difficulties in studying liver metabolism directly in humans, very little direct information as to the effects of carbohydrate ingestion on hepatic GP is available. The available data, however, all uniformly show that exogenous glucose reduces the demands on the liver. Glucose infusion reduces hepatic GP during low- and moderate-intensity exercise in humans.^{6,134} Furthermore, glucose ingestion inhibits the uptake of gluconeogenic precursors by the splanchnic bed during prolonged low-intensity exercise.¹³³ The potent effect of glucose infusion and carbohydrate ingestion at the liver is probably mediated, in large part, by a highly sensitive pancreatic hormone response.⁶

Postexercise Glucose Metabolism

Stimulatory effects of exercise on muscle glucose uptake can persist well after cessation of exercise. In contrast to moderate exercise, where all the glucose taken up by muscle is oxidized, the added glucose taken up after exercise is channeled into glycogen.^{6,85,99,135,136} The repletion of muscle glycogen after exercise occurs in two phases, which can be distinguished by their reliance on insulin and kinetics.^{137,138} In phase one, the sarcolemma permeability to glucose is elevated,¹³⁸ glycogen synthase activity is elevated,¹³⁸ and muscle glycogen is rapidly restored.^{137,138} This phase occurs immediately after exercise and is notable in that it does not require insulin.^{137,138} In the second phase, muscle glycogen has returned to near-normal levels and glucose uptake is no longer elevated in the absence of insulin. Phase two is characterized by a marked and persistent increase in insulin action.¹³⁸ Estimates of the duration of this second phase are highly variable. The increase in insulin sensitivity is probably more persistent after more extensive glycogen depletion and can be protracted by an absence of dietary carbohydrate.¹³⁹ It has been shown that glycogen repletion to preexercise levels requires approximately 24 hours in humans maintained on a high-carbohydrate diet, but may take as long as 8–10 days in the absence of dietary carbohydrate.¹³⁹ It has also been shown, using ¹³C-NMR spectroscopy, that muscle glycogen resynthesis can be slowed if the ingested medium is high in lipid content even if glucose content is equivalent.¹⁴⁰

As is the case during exercise, an increase in insulin binding to muscle insulin receptor is not necessary for the increase in insulin action following exercise,¹³⁸ indicating that post receptor events are responsible. Prior exercise enhances insulin-stimulated glucose uptake and glycogen synthase activity, but does not result in a greater increase in insulin receptor tyrosine kinase, Akt phosphorylation, or glycogen synthase kinase-3 phosphorylation.¹⁴¹ Muscle glycogen depletion, such as that which occurs with exercise, is a potent stimulant of muscle glycogen synthesis. The presence of the muscle insulin receptor may not even be necessary for the increased effects of insulin on muscle glucose uptake and glycogen synthase after exercise, implying that the effects of prior exercise are mediated by nonmuscle cells or by downstream signaling.¹⁴² It has been proposed that a postreceptor modification may be linked to the glycogen-depleting effect of exercise.⁹⁹ Nevertheless, the improved effect of insulin on glucose uptake can persist after exercise even when preexercise glycogen levels have been restored.¹³⁸

GLUT-4 is the primary means by which glucose enters the cell in the postexercise state. While GLUT-4 null mice have normal fed, fasted, and postexercise muscle glycogen content, the restoration of glycogen following a glucose load after exercise was markedly slowed.¹⁴³ It is possible that overexpression of GLUT-1 could compensate for any shortage of GLUT-4 in the plasma membrane as mice overexpressing this protein have increased muscle glycogenesis in the postexercise state.¹⁴⁴

The increase in muscle insulin sensitivity following exercise is reliant on a local factor since glucose uptake during one-legged cycling was increased across the exercised limb, but not the contralateral rested limb.¹³⁵ When extramuscular influences were eliminated by isolating and directly stimulating the muscle, however, insulin sensitivity was not increased.¹⁴⁵ The exercise-induced increase in insulin sensitivity seems, therefore, to require a local extracellular factor.¹⁴⁶ It is possible that a neurotrophic or paracrine factor released at or near the working muscle is required.

The cellular basis for the persistent increase in insulin sensitivity may, at least in part, relate to the demonstrations that skeletal muscle GLUT-4 protein,¹⁴⁷ glycogenin,¹⁴⁸ and hexokinase II activity⁶⁰ can be increased during recovery from acute exercise. Both these adaptations are accompanied by increases in the respective mRNA pools for these proteins.^{60,147} The increases in GLUT-4⁵⁹ and hexokinase II⁶⁰ mRNA levels appear to be due primarily to increases in the nuclear transcription rate of the genes for these proteins. Other posttranscriptional⁶⁰ and posttranslational⁵⁹ mechanisms may also be involved. One difference in the regulation of these proteins by exercise is that hexokinase II induction occurs more rapidly, and is initially more pronounced, than the induction of GLUT-4. Skeletal muscle GLUT-4 mRNA in the rat is unchanged immediately after 2 hours of electrical stimulation¹⁴⁹ or 90 minutes of treadmill exercise.⁶⁰ An increase in hexokinase II mRNA, on the other hand, is already present in rat muscle after 90 minutes of running.⁶⁰ Increases in skeletal muscle GLUT-4 mRNA and protein do occur but require a more strenuous exercise protocol or a longer exercise recovery period.¹⁴⁷ The more sensitive induction of hexokinase II as compared to GLUT-4 mRNA in muscle is reflected by differences in the transcription of their respective genes. An increase in hexokinase II gene transcription of almost threefold is seen immediately after 45 minutes of treadmill exercise in nuclei isolated from rat hindlimb muscles.⁶⁰ The transcription rate for the GLUT-4 gene is increased by only about 80% over basal rates and does not occur until 3 hours after exercise.⁵⁹

There can be a paradoxical decrease in glucose tolerance immediately following exhaustive or extremely intense exercise.^{150–152} This has been shown to correspond to elevated catecholamine and FFA levels^{151,152} and muscle damage,¹⁵⁰ as evidenced by elevated plasma creatine kinase and myoglobin.

In addition to the well-known adaptations in skeletal muscle, prior exercise can lead to persistent effects on splanchnic tissue. Studies in a dog model that provided access to gut and liver *in vivo* showed that prior exercise increased the intestinal absorption of an intraduodenal glucose load¹³⁶ and increased the intrinsic capacity of the liver to consume glucose (Fig. 27-6).¹⁵³ The increase in the ability of the liver to consume glucose is not due to a sensitization to the stimulatory effects of the arterial to portal vein glucose gradient.¹⁵⁴ Whether the effect on liver glucose uptake, like the effect on muscle glucose uptake, is related to an increase in insulin action is unknown. Studies using ¹³C magnetic resonance spectroscopy showed that ingestion of 1 g/kg of glucose or sucrose immediately after completion of prolonged moderate exercise caused liver

FIGURE 27-6. Net hepatic glucose fractional extraction (top) and b (bottom) following 150 minutes of moderate treadmill exercise equivalent period of rest. Data are mean $\pm$ SE; $n = 6$ in each group. I levels were fixed at $\sim 30 \mu\text{U/mL}$ using somatostatin with intraportal replacement and arterial blood glucose was clamped at $\sim 130 \text{ mg/dL}$ portal to arterial glucose gradient was $\sim 19 \text{ mg/dL}$ during hyperinsulinemic, hyperglycemic periods in both groups. The measurements made presence of a hyperglycemic, insulin-stimulated state were taken a 60-minute equilibration period, during which time a steady state achieved. *Indicates significantly greater values than corresponding steady period ($p < .05$). (Reprinted with permission from Helmlrich SP, et al.)

glycogen resynthesis to increase by 0.7 and 1.3 $\text{mg/kg}^{-1}\cdot\text{min}^{-1}$ respectively, over a period of 4 hours of postexercise recovery. There was no liver glycogen resynthesis over the same period when a placebo was ingested. The ability to replenish liver glycogen after exercise may be functionally important in performance of subsequent exercise as there was a significant positive correlation between liver glycogen content and exercise endurance.¹⁵⁵

EFFECTS AND MEDICAL BENEFITS OF EXERCISE IN DIABETES

The rationale and benefits of physical training in the general population were extensively reviewed in 1994 at the International Conference on Exercise, Fitness and Health.¹⁵⁶ The first conference on exercise and diabetes was organized in 1978 in Santa Ynes Vall, California.¹⁵⁷ We believe that this conference greatly stimulated this area of basic and clinical research, eventually demonstrating that exercise not only improves but can also prevent or delay the onset of diabetes, as described later in this chapter. This initial conference was followed by symposia in Olympia, Greece (1980), Burlington, Vermont (1983); Dusseldorf, Germany (1990); and frequent intervals thereafter. The 2000 American Diabetes Association Position Statement on "Diabetes Mellitus and Exercise" is

equivocally states that "with the publication of new clinical reviews, it is becoming increasingly clear that exercise may be a therapeutic tool in a variety of patients with, or at risk for diabetes," and that "all patients with diabetes" should be able to "benefit from the many valuable effects of exercise."¹⁵⁸ The founding of the International Diabetes Athlete Association (IDAA) in 1985 greatly stimulated the interest in exercise among diabetic populations around the world, and has established an information-, experience-, and knowledge-sharing system for diabetic people who are active in sports.¹⁵⁹ In 1988, diabetologists from 14 European countries, representing the European NIDDM Policy Group, met and prepared a consensus view of management of type 2 diabetes.¹⁶⁰ With respect to exercise, this document indicates overall benefits, improved glucose tolerance, decreased hyperinsulinemia, improved plasma lipoprotein profiles, and reduction of body weight and hypertension. Exercising muscle has been shown to increase glucose utilization by 7- to 20-fold compared to the resting muscle. In addition to the many general benefits of exercise enjoyed by nondiabetic individuals, exercise in type 2 diabetic individuals can potentially bring about medical improvements. These include better glycemic control, increased insulin sensitivity, reduced insulin requirement, improved plasma lipid profile and blood pressure, reduction in fat mass, preservation of lean body mass, and strengthened cardiovascular fitness.¹⁶¹ Persistent and well-controlled exercise programs are expected to help lower glycated hemoglobin levels, which is the key to prevention of many chronic diabetic complications. In recent years, the traditional bias against diabetic individuals to engage in high-intensity, competitive sports has been challenged by a growing number of successful athletes, including Olympic gold medalists and world champions, who had type 1 diabetes.¹⁶² However, the majority of diabetic individuals who are not professional athletes will benefit most by engaging in regular, aerobic exercise of moderate intensity. Due to the many pathologic, hormonal, and biochemical disparities, type 1 and type 2 diabetic individuals respond to and benefit from exercise with different clinical patterns as discussed below.

Exercise in Individuals with Type 1 Diabetes

The American Diabetes Association recommends that "all levels of exercise, including leisure activities, recreational sports, and competitive professional performance, can be performed by people with type 1 diabetes who do not have complications and are in good blood glucose control."¹⁵⁸

In type 1 diabetes, exercise should not be used for the sole purpose of improving unsatisfactory glycemic control. All efforts should be made to advise and support those type 1 diabetic patients who are motivated to exercise to do so under optimal conditions for performance and enjoyment and with minimal risk of causing acute complications. A number of studies have found that physical training can increase VO_2max ,¹⁶³ decrease insulin dose,¹⁶³ and reduce levels of HbA_{1c} . It is noteworthy that each of these studies achieved improvement of some, but not all parameters, which may be related to the differences in patient selection and training protocols. Small sample size and lack of adequate controls may also account for the discrepancy in results. Given the importance of diet and insulin therapy as determinants of glycemic control in type 1 diabetes, it is not surprising that glycosylated hemoglobin is little affected by increased physical activity. The importance of the general benefits of exercise, especially on the cardiovascular system, lends strong support to the promotion of physical training in type 1 diabetes.

Whether exercise improves insulin sensitivity in this particular population is still unresolved, but aerobic exercise in type 1 diabetic patients has been shown to substantially improve cardiorespiratory endurance, muscle strength, lipid profile, blood pressure, and glucose regulation.¹⁶⁴ Exercise training also reduces insulin requirement in these patients.¹⁶⁵ In general, exercise is safe and can be well tolerated in most patients even with 24–40 years of type 1 diabetes.^{164,166} The peak oxygen consumption, respiratory exchange ratio, heart rate, and cardiac output in these exercising diabetic people are not significantly different from those of nondiabetic subjects.¹⁶⁶ Exercise in type 1 diabetic patients needs to be properly prescribed and closely monitored while their insulin dosages are adjusted. Without these precautions, exercise in type 1 diabetic subjects may provoke excessive glucose counterregulation, impaired glucose disposal, and even severe clinical complications, such as life-threatening hypoglycemia.

It is well accepted that exercise enhances glucose uptake and reduces insulin requirement for the working muscle. This fact, however, should be construed by no means as a diminished importance of insulin during exercise. On the contrary, adjustment of proper insulin dosage becomes even more critical during exercise than in the resting state. In general, diabetics are able to meet the energy needs of exercise; however, it is often with less than the optimal balance of fuel usage. Both insulin sensitivity (SI) and glucose effectiveness (SG) are impaired in type 1 diabetes, even when glycemia is under apparent control.¹⁶⁷ Exercise stimulates release of catecholamines, among other counterregulatory factors, which can decrease SI in type 1 diabetes.¹⁶⁸ The metabolic response to exercise in type 1 diabetic subjects varies with age, fitness, type of exercise, and nutritional status. The metabolic abnormalities and complications accompanying the disease often render exercise difficult for some patients. Due to a left-shifted oxygen dissociation curve as a result of high levels of glycosylated hemoglobin and the high frequency of vasculopathy, oxygen delivery to the muscle may be impaired. Furthermore, the development of neuropathies in patients with long-standing diabetes may hinder work tolerance.

Individuals with type 1 diabetes rely on gluconeogenesis substantially more than nondiabetic individuals for glucose fuel to feed the exercising muscle. The exercise-induced increments in glucose utilization are, by and large, similar in individuals with and without diabetes. Nevertheless, a few differences exist. First, in healthy individuals, this increase is associated with a higher rate of metabolic clearance. In patients with poorly-controlled diabetes, it is a result of an increased mass action of exaggerated hyperglycemia coupled with a small increment in metabolic clearance.⁸² Second, a smaller percentage of the glucose utilized is completely oxidized in patients with diabetes, probably due to an impaired pyruvate dehydrogenase activity. This leads to an accelerated Cori cycle featuring augmented lactate release from muscle and augmented lactate-derived hepatic gluconeogenesis. Third, underinsulinization and exaggerated counterregulation result in increased mobilization and utilization of noncarbohydrate fuels, such as FFAs, especially in subjects with severe diabetes. Type 1 diabetes is also associated with a greater availability of ketone bodies for energy metabolism due to an increased splanchnic fractional extraction and a greater intrahepatic conversion of FFAs to ketone bodies as assessed by ^{14}C -oleic acid infusion.¹⁶⁹ The effects of insulin on muscle glucose utilization can be partly mediated by insulin's effects on fat metabolism.^{170,171} Exercise-induced increases in glucose uptake and clearance were markedly enhanced by suppression of FFA oxidation in alloxan-diabetic dogs⁸³ or suppres-

sion of both FFA oxidation and lipolysis in depancreatized dogs.¹⁷⁰ Suppression of lipolysis using acipimox reduced fat oxidation and increased carbohydrate oxidation during and after moderate exercise in patients with T2DM. Respiratory quotient (RQ) was elevated by acipimox during exercise. In contrast, heparin treatment increased plasma FFA levels by 150%, increased fat oxidation by 7%, and reduced carbohydrate oxidation by 29%. Insulin-deficient diabetes may also exhibit differences in intramuscular substrate metabolism in response to exercise.

Patients with diabetes deprived of insulin for 24 hours have decreased intramuscular glycogen storage and increased intramuscular fat storage. This shift in fuel storage leads to a greater metabolism of intramuscular fat and a diminished breakdown of intramuscular glycogen. By using ratio-labeled palmitate and glucose in combination with gas-exchange measurements, it was calculated that in the insulin-deficient depancreatized dog more than twice as much intramuscular fat, but only about 60% of the muscle glycogen, are used. Thus, glucose and fatty acids, as fuels for exercising muscle, are utilized in a reciprocal and complementary fashion. An important issue is that decreased fatty acid oxidation may facilitate glucose utilization and improve hyperglycemia in exercising diabetic people.^{83,170} Resistance exertions should be conducted under professional guidance. In patients with physical limitations, graded walking may be preferred. In those with low back pain, lower extremity arthritis, sensory loss, and other medical conditions, moderate-intensity swimming may be a good choice. When initiating a physical training program, all patients with type 1 diabetes should seek professional guidance from physicians, nurses, and/or diabetes educators.¹⁷²

Inadequate Insulinization

Individuals with type 1 diabetes require adequate insulinization for improvement of metabolic control. Insulin deficiency can cause serious metabolic decompensation in diabetic patients during exercise, which is manifested by aggravated hyperglycemia and ketosis. When type 1 diabetic patients deprived from insulin treatment for a prolonged period (18–48 hours) underwent a 3-hour bout of exercise, blood glucose rose further.¹⁷³ The worsening in hyperglycemia is due to an attenuated increase in glucose metabolic clearance in the face of rising GP that is generally similar or excessive when compared to nondiabetic subjects. Underinsulinization during exercise may also lead to further increases in FFA and ketone body levels.

Exercise as a form of physical stress invokes a surge of counterregulatory hormones, glucagon,^{83,173–175} epinephrine and norepinephrine,⁸³ and cortisol,^{83,173} all of which can exacerbate the diabetic state in an underinsulinized individual. The magnitude of increase in these hormones depends not only on the extent of insulinization and the physical fitness of the subject, but also on the intensity and duration of the exercise. Owing to the overresponsiveness of the counterregulatory system in diabetes, high-intensity exercise can be more deleterious to the diabetic state than moderate exercise of similar duration, as is described later.

Excessive counterregulation does not occur only during exercise, but is a general characteristic of stress response in diabetes. For example, a stress model induced by injecting carbachol into the third cerebral ventricle in normal dogs caused a surge of counterregulatory hormones and stimulated glucose utilization. The stress-mediated increase in glucose uptake was independent of insulin release and not mediated by adrenergic pathways. However, the same type of stress in diabetic dogs failed to increase glucose utilization,

resulting in markedly worsened hyperglycemia.^{176,177} This tance of glucose uptake to exercise could not be improved by normalization with basal or high insulin infusion rates, indicating that stress can offset glucose homeostasis even in the presence of hyperinsulinemia. However, similarly to exercise,⁸³ β -blockers improved glucose uptake and prevented hypoglycemia. This indicates that during severe stress, transient treatment with β -blockers could improve glucose homeostasis.¹⁷⁸ An unresolved, intriguing question is whether there are similarities in the mechanisms stimulating glucose utilization in stress and exercise, be under both conditions, glucose utilization increases despite release of counterregulatory hormones and without a concurrent increase in insulin release. Finding the mechanism for this intriguing observation may help improve glucose homeostasis in diabetics during stress.

When hypoinsulinemic, the diabetic liver becomes more sensitive to glucagon while the glucagon response to exercise is exaggerated.¹⁷⁵ Catecholamines clearly have potent peripheral effects in type 1 diabetic humans and dogs.⁸² In the total absence of insulin, catecholamines play an even more important role than glucagon in control of GP. The effects of catecholamines are related to the mobilization of FFAs to sustain gluconeogenesis and to the stimulation of glycogenolysis. These effects are minimized by β -blockers in insulin-infused type 1 diabetic subjects, and in insulin-deficient diabetic dogs.^{82,83} Adequate insulin therapy is critical in improving metabolic control and normalizing the excessive counterregulatory response to exercise in people with type 1 diabetes.

Overinsulinization

The most feared acute complication of exercise in patients with type 1 diabetes is hypoglycemia caused by relative overinsulinization, that is, an otherwise moderate dose of insulin becoming excessive during exercise. In normal individuals, physical exercise is associated with a physiologically regulated reduction in endogenous insulin release. This low rate of insulin secretion carries a number of physiologic benefits. One such benefit is protection against overinsulinization and excessive glucose utilization, because muscle glucose uptake is increased by both insulin-dependent and insulin-independent mechanisms. Another physiologic benefit lies in the unleashing of the glucagon stimulation of hepatic GP. In spite of reduced secretion, insulin delivery to the exercising muscle is not compromised because of accelerated blood circulation. Therefore, a moderate dose of insulin under nonexercising conditions can cause overinsulinization during exercise in the insulin-treated, exercising diabetic person. Relative or absolute overinsulinization may take place, due to the following factors:

1. Absorption of subcutaneously injected insulin accelerates during exercise.^{179,180}
2. Unlike endogenous insulin secretion, insulinemia due to exogenous injections does not fall during muscular work.
3. Exercise enhances insulin sensitivity in the skeletal muscle.¹⁸¹

Whatever the cause, overinsulinization diminishes hepatic GP while further increasing glucose utilization. Consequently, hypoglycemia ensues during or after exercise. It is also noteworthy that individuals with antecedent hypoglycemia may be at an increased risk for subsequent hypoglycemic attacks during exercise due to blunted neuroendocrine defense and impaired metabolic response with insufficient endogenous GP.¹⁸²

The time of day exercise is performed and the prevailing levels of insulin are of importance when considering appropriate measures to prevent hypoglycemia. The risk of exercise-induced hypoglycemia is lowest in the morning before insulin injection when low insulin levels usually prevail. However, this may be achieved at the cost of hyperglycemia. Exercise in the evening or afternoon carries a higher risk of nocturnal hypoglycemia due to enhanced insulin sensitivity extended beyond the exercise period when the muscle glycogen store continues to be replenished.¹⁸³

A reduction in insulin dosage in anticipation of exercise helps prevent hypoglycemia. Patients with diabetes undergoing intensive insulin therapy were able to avoid hypoglycemia during 45 minutes of postprandial exercise at 55% maximum oxygen uptake by reducing insulin treatment from 30–50%.¹⁸⁴ Patients with diabetes with 80% reduction in insulin dosage were able to exercise for nearly 3 hours without hypoglycemia, whereas a 50% reduction in insulin dosage allowed exercise for only 90 minutes.¹⁸⁵ In contrast to patients with tightly controlled diabetes, those with fasting hypoglycemia were able to perform sustained exercise with a less substantial reduction in insulin.¹⁸⁵ High-intensity exercise elicits a greater glucose-lowering effect than moderate-intensity exercise. The exercise intensity should be taken into consideration when adjusting preexercise insulin dosage. *In vivo* insulin sensitivity was increased in patients with type 1 diabetes up to 2 hours after one bout of exercise at 50% of maximal oxygen uptake for 30 minutes.

Instant ingestion of extra carbohydrate can effectively prevent and/or treat hypoglycemia, as glucose derived from exogenous sources is readily utilizable by the working muscle.^{183,186} The choice of carbohydrate supplements should exclude bulky food and include only rapidly absorbable carbohydrates ingested in small amounts to avoid exercising on a full stomach.¹⁸³ Injection of insulin into a nonexercising part of the body can help prevent an acceleration in insulin absorption.¹⁸³ In addition to insulin dose adjustments, the use of lispro insulin, a rapid- and short-acting formulation of insulin, may also be used to minimize the risk of hypoglycemia during and after exercise.¹⁸⁷

It is well known that the responses of glucagon and epinephrine to insulin-induced hypoglycemia are impaired in resting patients with type 1 diabetes and in alloxan-diabetic dogs.¹⁸⁸ However, the secretion of counterregulatory hormones was found to be adequate in the face of hypoglycemia during a long-distance run in reasonably well-controlled, well-trained subjects with diabetes, but without long-term complications.¹⁸⁹ It appears that the degree of diabetic control and state of physical fitness may influence the difference in counterregulatory response to hypoglycemia.

Although a fall in insulin is essential for the normal metabolic response to exercise, it is not clear whether this is the case in subjects with type 1 diabetes receiving a peripheral insulin infusion (Fig. 27-7).^{180,190} When patients with type 1 diabetes were exercised during a constant insulin infusion that maintained normoglycemia, the response of GP was either insufficient or adequate^{180,190} to prevent a fall in glycemia. The actions and mechanisms of peripheral insulin infusion on hepatic GP in these patients during exercise are not clear. It should be noted that in diabetic dogs and humans, at least during rest, insulin exerts its inhibition of hepatic GP primarily through a peripheral mechanism.^{191,192} The responses seen in diabetes, therefore, cannot always be extrapolated to normal physiology.

The three panels of Fig. 27-8 summarize the interactions of insulin and glucagon in regulating glucose turnover in exer-

FIGURE 27-7. Glucose turnover: glucose disappearance (**upper panel**) and glucose production (**lower panel**) at rest, at 45 minutes of exercise, and 60 minutes recovery for the normal controls. Insulin-infused (IV), and subcutaneous (SC) insulin-treated diabetics. (Reprinted with permission from Zinman B, et al.¹⁸⁰)

cising patients with type 1 diabetes and in depancreatized dogs.^{82,170,174,175,179,180;}

1. During constant intravenous infusion of insulin, glucose homeostasis is preserved because GP and utilization are balanced as in nondiabetic subjects.
2. Due to the direct or indirect (FFA-glucose cycle) effects of insulin deficiency,^{170,174} exercise does not stimulate glucose utilization adequately, and hence, the exercise-induced increase in hepatic GP leads to or enhances hyperglycemia, a key factor restraining metabolic glucose clearance during exercise.¹⁷⁴
3. Absolute or relative overinsulinization, due to absorption of subcutaneous insulin injected before exercise, results in inhibition of hepatic GP, enhanced peripheral glucose uptake, and a fall in blood glucose levels.¹⁸⁵

Intense Exercise in Type 1 Diabetes

The effect of intense exercise was examined in patients with type 1 diabetes whose glycemia was normalized or kept moderately elevated by constant insulin infusions maintained overnight and during the experimental period. As in normal subjects, it ap-

FIGURE 27-8. Scheme indicating changes in glucose fluxes during exercise in insulin-treated diabetes.

pears that catecholamines are the main regulators of GP during intense exercise and that they induce a relative inhibition of glucose utilization. The main difference in glucose homeostasis between normal subjects and those with diabetes was that the elevation in glycemia induced by exercise was sustained throughout the postexercise period in both normoglycemic and hyperglycemic individuals with type 1 diabetes. During this prolonged period of hyperglycemia, the metabolic clearance rate (MCR) of glucose was reduced. However, hyperglycemia during intense exercise in both groups of patients with type 1 diabetes fully compensated for the low MCR (decreased efficiency of glucose extraction) such that overall glucose utilization was the same as in control subjects (Fig. 27-9).²⁸ Thus, hyperglycemia appears to be an adaptive phenomenon to reduced MCR, which ensures that during strenuous exercise, glucose delivery to the muscle is kept constant. This corresponds to similar observations in diabetic dogs subjected to moderate exercise.^{170,174} On a cellular level, the efficiency of glucose uptake is related to the number of glucose transporters in the plasma membrane.¹⁹³ The observation that hyperglycemia decreases the number of glucose transporters in the plasma membrane also supports the notion of an adaptive effect of hyperglycemia.¹⁹³

This postexercise hyperglycemia can be normalized by an additional postexercise administration of insulin. Postexercise hyperinsulinemia was required to further increase MCR and gradually return plasma glucose concentrations to preexercise levels.^{28,194} Therefore, special strategies, differing from those for less strenuous exercise, are required for management of insulin therapy in type 1 diabetes during and after intense exercise.

The difference from moderate exercise is largely accounted for by the difference in catecholamine responses. As noted, the stimu-

lation of muscle glycogenolysis increases the glucose-6-phosphat which in intense exercise is likely to be sufficient to restrain the uptake of circulating glucose and account for the hyperglycemia. Consistent with this explanation is the effect of β -adrenergic receptor blockade during stress¹⁷⁸ or moderate exercise in dogs,⁸³ and in intensely exercised normal¹⁹⁵ and type 1 diabetic subjects¹⁹⁶ in who β -blockade increased metabolic clearance.

Effect of Hyperglycemia: Possible Protection of Muscle Against Excessive Glucose

The effect of hyperglycemia on metabolic glucose clearance (MCR) is of pivotal importance during exercise in diabetes. This section summarizes the effects during both rest and exercise. Decreased MCR in hyperglycemia may reflect a protective mechanism against excessive glucose in the muscle. It is tempting to speculate that this is the reason that muscle does not have the diabetic complications seen in so many other tissues. Restoration of normal glycemia by phlorizin treatment normalizes glucose transporters in plasma membrane. Importantly, this effect of normalization of plasma glucose occurs without any changes in plasma insulin. In the same experiments, hyperglycemia also suppressed GLUT-4 mRNA and normoglycemia brought about partial restoration. The conclusion is that hyperglycemia itself suppresses both gene expression and translocation of the GLUT-4 protein (Fig. 27-10).¹⁹³ This adaptive mechanism of glucose uptake could also be demonstrated in the absence of insulin in glucose-perfused rat hindquarter. Glucose uptake was maintained both during hyper- and hypoinsulinemia due to decreased or increased GLUT-4 transporter and glucose clearance, respectively.¹⁹⁷

Similarly, normalization of glycemia with phlorizin in alloxan-diabetic dogs increases MCR, while glucose uptake is unchanged. This applies both to resting conditions^{188,198} and to exercise (Fig. 27-11).^{199,200} This mechanism of self-regulation also explains observations in streptozocin-diabetic rats where endogenous pH and energy stores measured with nuclear magnetic resonance (NMR) techniques and the activity of pyruvate dehydrogenase during rest and muscular contraction were normal, not only in insulin-treated rats but also in rats with insulin treatment discontinued for 3 days (Fig. 27-12).²⁰¹

Exercise in Individuals with Type 2 Diabetes

It is well documented that chronic exercise is particularly important in type 2 diabetes, since it can prevent the onset of the disease and improve glycemia and other metabolic parameters. Glucoregulation, which has been extensively studied in type 1 diabetes, has scarcely been studied in type 2 diabetes. During exercise in type 2 diabetes, plasma glucose declines. In studies in which insulin levels failed to decrease during exercise, perhaps due to neuropathy, the decline in plasma glucose was due to a blunted increase in GP.²⁰² However, in a study in which insulin levels decreased, greater than normal rates of glucose utilization were found due to residual mild hyperglycemia, because glucose clearance increased similarly to control subjects.^{203,204}

There is a close association between the metabolic syndrome, or syndrome X, and type 2 diabetes. Indeed, many individuals with obesity, dyslipidemia, hyperinsulinemia, and hypertension eventually develop type 2 diabetes. Most patients with type 2 diabetes lead a sedentary lifestyle and have a low $\text{VO}_{2\text{max}}$.¹⁶⁵ Therefore, physical exercise is one of the three principal therapeutic measures

HYPERGLYCEMIA FULLY COMPENSATES FOR DEFECTIVE MCR IN INSULIN INFUSED HYPERGLYCEMIC IDDM'S

FIGURE 27-9. Effect of intense exercise in IDDM subjects whose glycemia was normalized (■) or kept moderately elevated (□) by constant insulin infusions maintained overnight and during the experiment.

recommended, along with diet and weight control and hypoglycemic medicines, for type 2 diabetic patients.^{156,165}

DIABETES PREVENTION

Historically, a number of factors have shifted emphasis from the use of physical activity for diabetes treatment to its use for diabetes prevention. They include difficulty in obtaining compliance with an exercise program in middle-aged and elderly individuals,

the variable response of patients with established type 2 diabetes, and the fact that vascular complications of diabetes are present in many patients at the time of diagnosis. For these reasons, it was suggested that an optimum target population for an exercise program might be people at increased risk for type 2 diabetes such as individuals with impaired glucose tolerance and/or insulin resistance.^{205,206} In keeping with this hypothesis, cross-sectional studies in Melanesian and Indian Fijian men²⁰⁷ by Taylor and colleagues, other populations,²⁰⁸ and in college alumni,²⁰⁹ demonstrated an

FIGURE 27-10. A. Effect of normalization of glycemia on cytochalasin B binding and GLUT-4 glucose transporters in hyperglycemic normoinsulinemic diabetic rats. The isolated fractions were isolated for protein and 5-nucleotidase activity. Forty micrograms of protein-isolated membrane fractions were analyzed by Western blot using an anti-GLUT-4 antibody. The blots were quantified by laser densitometry and the results were plotted in arbitrary units relative to the values in the plasma membrane of control animals. Plasma membrane glucose transporters were suppressed by diabetes and restored by normalization of glucose with phlorizin. Normalization of glucose with phlorizin restores cytochalasin B binding but not the GLUT-4 transporters in internal membranes. **B.** GLUT-4 mRNA is suppressed by diabetes and partially restored by normalization of glucose with phlorizin. (Reprinted with permission from Dimitrakoudis D, Vranic M, Klip A: Effects of hyperglycemia on glucose transporters of the muscle: Use of the renal glucose reabsorption inhibitor phlorizin to control glycemia. *J Am Soc Nephrol* 1992;3:1078.)

inverse relationship between physical activity and risk of type 2 diabetes, as did later studies of male college alumni by Helmerich and coworkers²¹⁰ (Fig. 27-13) and in nurses²¹¹ and male physicians²¹² by Manson and coworkers. In the college alumni and male physicians, the risk reduction was particularly pronounced among obese men.

Further proof of the benefit of exercise in diabetes prevention came from two later studies, in which the effect of 5–6 years of increased physical activity was examined prospectively in several hundred patients with impaired glucose tolerance in China (DaQuing)²¹³ (Table 27-1) and Sweden (Malmo).²¹⁴ In Malmo, therapy consisted of dietary advice during the first 6 months and exercise throughout. In DaQuing, the effects of exercise, diet, and the two in combination were independently evaluated. In both studies, progression to diabetes over 5–6 years was diminished by 30–50% in all intervention groups, with no additive effect of exercise plus diet observed.²¹³ Plasma triglycerides and insulin levels were also reduced in the Malmo exercising subjects.²¹⁴ A critical finding in the Malmo study was that after 12 years, overall mortality due to ischemic heart disease and other causes was diminished in the exercise group to levels similar to those of nondiabetic control subjects.²¹⁵ Thus, an emerging body of evidence suggests that in people with impaired glucose tolerance, exercise can be efficacious in preventing, or at least retarding progression to, diabetes, and in diminishing overall mortality. Of particular note is that lifestyle changes that include exercise or exercise and diet, which also increase insulin sensitivity, prevent or at least substantially delay the progression of individuals with impaired glucose tolerance to overt type 2 diabetes.²¹⁶ The Diabetes Prevention Program (DPP) also showed this. In a randomized clinical trial of diabetes prevention in 3234 overweight men and women aged 25–85 years

with impaired glucose tolerance, who exercised 150 minutes week (corresponding to a brisk walk) and reduced their weight 7%, there was a 58% reduced risk of developing type 2 diabetes. Logic suggests that this is somehow related to exercise's effect enhancing insulin action and reversing some of the risk factors associated with the metabolic syndrome, or of lowering blood glucose levels independent of insulin (e.g., by directly stimulating glucose utilization by muscle). This, however, remains to be proven.

Insulin resistance is a common clinical feature of type 2 diabetes that can be related to receptor and/or postreceptor defects. Intriguingly, many individuals with type 2 diabetes exhibit normal even slightly above normal rates of glucose utilization and normal splanchnic glucose output during exercise.²⁰⁴ However, muscle lactate output during exercise was elevated twofold and muscle glycogen store was one-third lower in these patients in comparison to the nondiabetic control subjects, indicating higher rates of glycolysis and glycogenolysis.²⁰⁴ This suggests that muscle insulin resistance in at least part of the type 2 diabetic population involves defects in glucose oxidative metabolism, the steps downstream to those of glucose transport and glycolysis. Therefore, to understand the effects of exercise in type 2 diabetes, the severity of the disease and the specific treatments the patient receives must be taken into account. Bicycle ergometer exercise for 30 minutes stimulates sympathetic hypersensitivity in patients with type 2 diabetes at fasting hyperglycemia and hyperketonemia, but not in those who were well controlled.²¹⁶ Some individuals with type 2 diabetes with postabsorptive hyperglycemia and near-normal basal insulin secretion display a significant fall in glycemia following exercise due to a failure of insulin to decrease during exercise. These patients have a defect in control of insulin secretion when challenged

FIGURE 27-11. A. Glucose utilization and metabolic clearance rates of plasma glucose in dogs before, during, and after 60-minute treadmill exercise (100 m/min, 5% slope). Experiments were conducted in four dog protocols consisting of one protocol with normal control dogs (C, O) and three protocols with alloxan-diabetic dogs studied under conditions of hyperglycemia (DH, γ), and during acutely induced normoglycemia (<160 minutes) with either insulin ($2.6 \pm 0.6 \text{ pmol}\cdot\text{kg}^{-1}\cdot\text{min}^{-1}$, DI (■)) or phlorizin ($50 \text{ kg}\cdot\text{min}^{-1}$, DP). Values are presented as mean $\pm$ SE from six experiments in each protocol. During hyperglycemia metabolic clearance of glucose was markedly suppressed during rest and exercise. It was normalized with normoglycemia and independently of insulin or FFA levels—glucose utilization was only slightly decreased in hyperglycemic dogs, reflecting the balance between mass effect of hyperglycemia and suppressed clearance. B. Correlation between rates of FFA turnover and lactate concentrations in all four dog protocols consisting of normal control dogs and alloxan-diabetic dogs studied under conditions of hyperglycemia and during acutely induced normoglycemia (<160 minutes) with either insulin or phlorizin. Plotted data indicate the mean $\pm$ SE during the basal period, exercise period, and recovery period for each protocol ($r = 0.72$, $p < .001$). Increased FFA turnover did not affect glucose uptake, but it decreased glucose oxidation—a reflection of lactate release.

FIGURE 27-12. Changes in intracellular pH in gastrocnemius muscle during stimulation at 1 and 5 Hz and during the initial recovery period for insulin-treated diabetic ($\bullet$), untreated diabetic ($\blacksquare$), and diabetic animals from which insulin therapy was withdrawn for 72 hours prior to study ($\blacktriangle$). Values are shown as mean $\pm$ SE for six experiments in each study group. (Reprinted with permission from Challis RAJ, et al.²⁰¹)

both with glucose (inadequate increase) and exercise (inadequate decrease). The latter could be a consequence of hyperglycemia prevailing over the adrenergic stimulation, or part of the intrinsic abnormality of islet β -cell function, or of neuropathy. In addition, hyperglycemia, acting synergistically with insulin, can suppress GP and sustain a normal rate of peripheral glucose uptake.

In general, exercise is associated with improvements in insulin action and glucose metabolism. Twelve to 16 hours after a single bout of glycogen-depleting exercise, hepatic insulin sensitivity was enhanced in patients with type 2 diabetes.¹⁸¹ The prior exercise reduced basal hepatic GP by 25%, while a low-dose insulin infusion suppressed it by 85%. Peripheral insulin sensitivity was also enhanced, which was reflected by an increased rate of nonoxidative glucose disposal.¹⁹¹ In a 10-year lifestyle modification program, persistent physical exercise has resulted in a significant improvement in glycated hemoglobin, blood pressure, and plasma triglycerides profile.¹⁶⁵ In a recent study, patients with type 2 diabetes with a mean body mass index of 30.2 underwent a 2-month exercise program that consisted of a twice weekly supervised 45-minute cycling at 75% VO_2 peak. This resulted in a 41% increase in VO_2 peak and 61% increase in glucose disappearance during an intravenous glucose tolerance test (IVGTT). The improvement was associated with a reduction of visceral adipose tissue (VAT) that was greater than the loss of subcutaneous fat (Fig. 27-14).²¹⁸ Thus, in obese individuals with type 2 diabetes, regular- and moderate-intensity exercise can lead to improvements in both obesity and insulin sensitivity.²¹⁸ These studies emphasize the significance of exercise in improving energy fuel metabolism, and its importance as an adjuvant therapy for type 2 diabetes.

Patient participation may be affected by length and severity of the illness that in turn affect the medical benefits of exercise. For example, a high incidence of complications can preclude participation for some patients, but in some studies, no complications or dropouts were reported with exercise training in type 2 diabetic patients for 3 months.^{219,220}

Type 2 diabetic patients who have no major vascular complication should be able to exercise as normal people. Single bouts of

FIGURE 27-13. Age-adjusted incidence rates and relative risks of T2DM among 5990 men, based on 1962 data for the physical activity index in relation to the body mass index (A) and any history of hypertension (B). Each block represents the relative risk based on the rate of T2DM per 10,000 person-years of follow-up, with the risk for the tallest block set at 1.0. The numbers on the blocks are the incidence rates of T2DM, and the numbers of patients with T2DM are shown below in the corresponding grid. (Reprinted with permission from Helmrach SP, et al.²¹⁰)

exercise in type 2 diabetic men have been shown to enhance peripheral and splanchnic insulin sensitivity for up to 16 hours.¹⁸¹ Although the incidence of hypoglycemia is much lower in the type 2 than in the type 1 diabetic population, the use of sulfonylurea and insulin in patients with type 2 diabetes increases the susceptibility to this complication, especially among those who exercise after taking the drugs.²²¹ It is interesting that in the majority of patients with type 2 diabetes, exercise-induced glucose utilization was not impaired but actually greater than in the nondiabetic individuals. In the meantime, the exercise-induced rise in hepatic GP can be restrained by the prior use of hypoglycemic drugs, including sulfonylureas, insulin, and inhibitors of FFA oxidation. The actions of sulfonylurea drugs and exercise can potentiate each other and the hypoglycemic responses are further enhanced by sulfonylurea-induced insulin secretion, which restrains hepatic GP and reduces glucose supply to the working muscle.²²² When glyburide was given to normal subjects before exercise, insulin levels increased about twofold and blood glucose levels fell to about 50 mg/dL.²²³ The nadir in blood glucose levels was deeper and occurred more promptly than when glyburide was administered to resting subjects.

Thus, normoglycemic patients with type 2 diabetes may be at increased risk of developing hypoglycemia if they exercise 1–2 hours after ingesting sulfonylureas. In general, however, type 2 diabetic individuals should avoid high-intensity exercise, which induces an exaggerated rise in counterregulatory hormones. Excessive hyperglycemia can be triggered or worsened by a greater increase in C than glucose utilization.

An appropriate exercise program should be a powerful adjunct to the diet and drug therapies to improve glycemic control, reduce cardiovascular risk factors, and increase psychological well-being in individuals with type 2 diabetes. It has been clearly demonstrated that leisure-time physical activity, expressed in kilocalories expended per week in walking, stair climbing, and sports, was inversely related to the development of type 2 diabetes (Fig. 27-14).²¹ The incidence rates declined as energy expenditure increased from less than 500 kcal to 3500 kcal. For each 500-kcal increment in energy expenditure, the age-adjusted risk of type 2 diabetes was reduced by 6%.²¹⁰ In most patients, the benefits of exercise substantially outweigh the risks. However, attention must be paid to minimizing potential exercise complications.

TABLE 27-1. Effects of 6 Years of Diet and Exercise Therapy on Progression to Type II Diabetes in Lean and Overweight Patients with Impaired Glucose Tolerance (DaQuing Study)

	Control	Diet	Exercise	Diet and Exercise
Lean				
n	50	55	57	46
Initial BMI (kg/m ²)	22.4	21.8	21.7	22.3
Percent diabetic (6 yrs)	30	21	15*	16*
Overweight				
n	83	75	84	80
Initial BMI (kg/m ²)	28.5	28.3	27.9	28.6
Percent diabetic (6 yrs)	60	36*	43*	42*

*Significantly different from control group, $p < 0.05$.

Roughly equal numbers of men and women, ages 44–46 at the onset of the study, were followed in each group. Results are means for indicated number of subjects. Diet consisted of a decrease in ethanol and refined sugar intake and an increase in vegetables in the lean young group and a similar diet with reduced calories in the overweight subjects. Exercise consisted of an increase in daily leisure physical activity of varying intensity. Lean and overweight groups experienced small increases and decreases in body mass index, respectively, over 6 years. Body fat and its distribution were not measured, or plasma insulin or triglyceride levels. Blood pressure was measured but not reported.

Adapted from Pan et al.²¹³

FIGURE 27-14. In overweight, type 2 diabetic patients (BMI: 30.2 ± 0.9 kg/m²), physical training with 45 minutes of cycling at 75% of $\dot{V}O_2$ peak twice weekly for 2 months resulted in a marked (48%) loss of visceral adipose tissue (VAT). The loss of VAT was associated with a significant improvement in insulin sensitivity indicated by the glucose disposal during an intravenous glucose tolerance test (Kitt). (Reprinted with permission from Mourier A, et al.²¹⁸)

Effect on Insulin Sensitivity in Nondiabetics

The general effects of exercise on improvement of glucose tolerance and insulin sensitivity have been well documented.²²⁴ Insulin action in trained nondiabetic distance runners was enhanced in muscle, liver, and adipose tissue (Fig. 27-15).²²⁴ These effects of training are probably specific for aerobic exercise. Interestingly, no difference in specific binding of insulin to its receptor on monocytes was noted between the two groups. The increased insulin effect is primarily mediated by postreceptor events, such as increased glucose transport and intracellular metabolism. Enzyme activities for both glycogen synthesis and glucose oxidation are stimulated by physical training. Decreased adiposity and increased muscle mass, due to long-term training, can also contribute to improvement in insulin sensitivity. Insulin levels are lowered as a result of enhanced insulin sensitivity. Single bouts of exercise in untrained nondiabetic subjects are also associated with increased insulin sensitivity, presumably due to depletion of muscle and liver glycogen stores. Single bouts of exercise can also decrease insulin resistance in obese normoglycemic and obese type 2 diabetic subjects, probably related to improvements at both insulin receptor and postreceptor levels.

The effect of exercise on insulin sensitivity may be dependent on specific types of physical work. Strength training, for example, results in a net increase in submaximal insulin-stimulated glucose disposal and glucose tolerance that is proportional to the increased muscle mass and probably does not represent an increase in insulin sensitivity *per se*. Cycling at 70% $\dot{V}O_{2\max}$ and 4 hours per week for 12 weeks did not significantly affect insulin-stimulated glucose disposal in either lean and obese nondiabetic men, or diet-controlled type 2 diabetic patients.²²⁵ There are many other effects of training that can directly or indirectly affect carbohydrate metabolism during rest and exercise. One study²²⁶ showed that ath-

FIGURE 27-15. Mean $\pm$ SE values for basal, maximum, and insulin-stimulated glucose transport in adipocytes isolated from control (open bars) and trained (hatched bars) individuals. (Reprinted with permission from Rodnick KJ, et al.²²⁴)

letes have a larger capacity to secrete epinephrine in response to a variety of stimuli during rest.

The metabolic benefits of physical training can also be appreciated from observing the effects of cessation of training or bed rest. It is known that exercise-trained people have a reduced insulin response to a glucose load. As rapidly as 14 days after cessation of exercise training, this insulin response increased. However, rates of whole-body glucose disposal were not different between exercising and inactive states, indicating a large increase in insulin resistance due to inactivity.²²⁷ A 7-day bed rest also affected insulin responsiveness of protein metabolism in humans.²²⁸ After bed rest, subjects exhibited decreased glucose tolerance, increased endogenous insulin secretion, and a negative nitrogen balance compared with the control period. Because negative nitrogen balance and skeletal muscle atrophy occurred in the six rested subjects in the absence of changes in the two indices of protein breakdown used in this study, it seems likely that muscle protein synthesis was inhibited when compared with the period before bed rest.

Studies also suggest that exercise can positively impact a population of insulin-resistant, normal-weight individuals.²²⁰ These individuals are not obese on the basis of weight and height, but are hyperinsulinemic, insulin resistant, and predisposed to type 2 diabetes, hypertriglyceridemia, and coronary heart disease. The specific factors associated with insulin resistance in this population are central fat distribution, inactivity, and a low $\dot{V}O_{2\max}$. Long-term exercise and diet can significantly diminish their incidence of diabetes.²²⁰

Effect on Insulin Sensitivity in Patients with Diabetes

Insulin binding to skeletal muscle in type 2 diabetic subjects was unaffected, but glycogen synthase activity was increased by training.¹⁶³ However, hepatic insulin sensitivity, as judged by suppression of hepatic GP, was not affected by training.²²⁹ When type 1 diabetic patients undergo exercise training that significantly increases their maximum oxygen consumption, glucose uptake in

response to a hyperinsulinemic euglycemic clamp is increased markedly.²²⁹ Studies in streptozocin-diabetic rats indicate that the ability to adapt to chronic exercise in insulin-deficient states may depend on the severity of the condition. Mildly diabetic rats increase insulin sensitivity in response to exercise training, whereas severely diabetic rats do not show this change.²³⁰

Studies in patients with type 2 diabetes have shown that an exercise training program that is feasible for most individuals can cause an improvement in glucose tolerance²¹⁹ and lower glucose-stimulated insulin levels.²¹⁹ Insulin sensitivity, as assessed by glucose disposal during hyperinsulinemic euglycemic clamps, improves with exercise training.²¹⁹ By combining euglycemic clamps, infusion of radioactive glucose, and measurement of glucose metabolic rate, it is possible to differentiate between glucose oxidation and glucose storage, because the latter is a nonoxidative pathway. A combined exercise training and diet program increased the total glucose disposal rate during an insulin clamp in type 2 diabetes by approximately 27%, due primarily to an accelerated rate of nonoxidative carbohydrate disposal (storage) (Fig. 27-16).²³¹ In contrast, diet alone did not affect glucose storage. Exercise alone does not appear to normalize muscular insulin sensitivity in insulin-resistant states. However, diet and exercise together may correct this condition.²³² In the perfused hindlimb of trained and sedentary insulin-resistant obese Zucker rats, training and a high-carbohydrate diet independently increased glucose uptake above that in sedentary, obese Zucker rats (on a high-fat diet) but still below that in lean control rats. A combination of high-carbohydrate diet and training had a synergistic effect. Thus, it appears that the combination of diet and exercise has a more

physiologic metabolic effect than diet alone. Basal and insulin-suppressed hepatic glucose output was also reduced by diet and training, but no more than by the diet program alone. Training programs lead to an improvement in insulin sensitivity in obese subjects even without concurrent weight loss or change in body composition (Fig. 27-17).²¹⁹ Nevertheless, since weight reduction by itself can also improve insulin sensitivity, it is likely that exercise training that results in loss of body fat will yield optimal results on carbohydrate metabolism.

Although insulin sensitivity is improved and muscular metabolic capacity is increased, it is unresolved whether glycemic control is effectively improved in trained individuals with type 2 diabetes. Indeed, there was no improvement in glycosylated hemoglobin levels, glycosuria, or fasting plasma glucose levels following training programs that resulted in significant increments in maximal oxidative capacity.²³³ In contrast, training can improve glycemic control in type 2 diabetes. It is important to note that individuals with different degrees of insulin resistance do not adapt to training in the same way. For example, training in insulin-resistant conditions characterized by high rates of insulin secretion can lead to a decrease in the release of this hormone.²¹⁹ On the other hand, training in subjects with insulin resistance and low insulin secretion has been shown to increase the rate of insulin secretion.²¹⁹ Finally, an improvement in insulin action in trained diabetic and nondiabetic subjects could be due to the cumulative effects of single exercise bouts rather than to long-term adaptation to exercise training.²³⁴ This is based on two lines of evidence. First, the effects of training on insulin action are rapidly reversed by inactivity, whereas the effects of training on oxygen uptake and lean

FIGURE 27-16. Carbohydrate disposal by nonoxidative processes, "storage." The single asterisk indicates the significant increase in estimated storage within the group in the dietary therapy plus physical training group ($p < .05$), and the double asterisk shows the significant reduction in the group given dietary therapy alone. (Reprinted with permission from Bogardus C, et al.²³¹)

FIGURE 27-17. Glucose disposal in diabetic subjects ($n = 10$) and controls ($n = 13$) during euglycemic clamp before (hatched bars) and after (open bars) physical training for 3 months, 3× weekly 50-minute alternate heavy (80%–90% $\text{VO}_{2\text{max}}$) and light periods. There was no change in BW, cell mass, or adipose cellularity. (Reprinted with permission from Kratkowski M, et al.²¹⁹)

body mass are more sustained.²³⁴ Second, an acute bout of exercise and exercise training share similar effects.¹⁸¹

Effects on Muscle and Adipose Tissues

The skeletal muscle is the major site of the increase in insulin action that occurs with training, due to its large mass of insulin-sensitive tissue and its fundamental role during physical work. Skeletal muscle in trained rats is more insulin sensitive than in sedentary control animals, due mainly to increased glucose oxidation.⁸⁰ Hyperinsulinemic euglycemic clamps combined with the 2-deoxy-glucose technique demonstrated an increase in maximal insulin-stimulated glucose metabolism in soleus and red gastrocnemius, and an increased insulin sensitivity in soleus, gastrocnemius, extensor digitorum longus, and diaphragm in exercise-trained rats compared with sedentary control rats.^{80,156} The increase in insulin action in skeletal muscle during habitual exercise may be due in part to an increase in insulin binding to its skeletal muscle receptor. It is surprising, however, that for similar amounts of bound insulin, trained rats had a decrease in the activity of the tyrosine kinase activity.^{235,236} Skeletal muscle adapts to aerobic exercise training so that it more readily uses fuel and oxygen. Physical training greatly enhanced mitochondrial oxidative enzyme activities, which last 4–6 weeks following the cessation of training in both type 1 and type 2 diabetic individuals.²³⁷ Streptozocin-diabetic rats have deficits in cytoplasmic and mitochondrial enzyme in muscle fibers, which are increased by training. In type 1 diabetic patients, training programs can lead to increases in skeletal muscle citrate synthase and succinate dehydrogenase that parallel an increase in insulin sensitivity.²³⁸ Improvement in insulin sensitivity with exercise training is associated with upregulated enzymes responsible for the phosphorylation, storage, and oxidation of glucose, and also with conversion of fast-twitch glycolytic IIb fibers to fast-twitch oxidative IIa fibers that are more insulin sensitive.²³⁹

It is well documented that both insulin and exercise translocate GLUT-4 from intracellular sites to the plasma membrane. The effect of insulin is more pronounced in red than in white muscle.²⁴⁰ The translocation from internal membranes to the muscle transverse tubules is at least as important as the transfer to plasma membrane²⁴¹ because the area of transverse tubules that penetrates the various muscle structures is much larger than that of plasma membrane. Swimming or free-wheel running induces rapid increases in the expression of the insulin-sensitive GLUT-4 protein and enhancement of glucose transport capacity and insulin-induced glycogen storage in the muscle in the normal rat.²⁴² In male patients with type 1 diabetes, acute exercise (3 hours at cycling) decreased cellular GLUT-4 mRNA content, while GLUT-4 protein content remained unchanged in the quadriceps femoris.²⁴³ In type 2 diabetic patients, physical training increased both muscle GLUT-4 protein and mRNA.²⁴⁴ However, human studies thus far could only measure total GLUT-4 content but not translocation of GLUT-4. Since glucose transport does not depend on the total cellular amount of GLUT-4 but on plasma membrane abundance of this protein, the human studies are not conclusive.

A recent study provided compelling evidence that regular exercise results in a marked preferential reduction (48%) in central obesity and a significant increase (23%) in thigh muscle tissue area, both of which help improve insulin resistance in type 2 diabetes.²¹⁸ Another new role of insulin is to induce vasodilation in skeletal muscle and increase muscle blood flow, leading to an increase in blood glucose extraction by the muscle.²³⁹ It is known that a re-

duced ability of insulin to vasodilate skeletal muscle contributes to insulin resistance in type 2 diabetes. Exercise training has been found to improve both muscle blood flow and glucose extraction in response to insulin.²³⁹

Changes in muscle capillary density can also affect insulin sensitivity by altering the exposure of muscle to insulin and glucose. In the rat, muscles with highest blood flow are the most insulin sensitive.²⁴⁵ In humans, muscle capillary density is strongly correlated to the total glucose disposal rate during a hyperinsulinemic euglycemic glucose clamp.²⁴⁶ However, postexercise muscle blood flow was 40.1 mL/min/100 g of tissue in the nondiabetic subjects and was significantly reduced in 10 type 1 diabetic (25.7 mL/min/100 g) and 11 type 2 diabetic patients (14 mL/min/100 g).²⁴⁷ Muscle capillary density was not improved by exercise training in the diabetic patients,²⁴⁸ although it increased significantly (50%) in nondiabetic athletes.

In addition to skeletal muscle, adipose tissue represents another site of adaptation to training. Regular physical activity increases insulin-stimulated glucose uptake,^{80,249} oxidation,⁸⁰ and incorporation into fatty acids⁸⁰ in rat adipocytes. The improvement of insulin action may relate to the reduced fat cell size after physical training. One such study demonstrated that insulin-stimulated 2-deoxyglucose uptake and 1-¹⁴C-glucose oxidation in adipocytes were highly correlated to fat cell size in exercise-trained, sedentary, and calorie-restricted sedentary rats. The increase in insulin action in adipocytes of trained rats occurs in the absence of any changes in insulin binding, indicating a modification in a postbinding event.

Exercise and Cardiovascular Health in Diabetes

Regular aerobic exercise results in significant improvements in lipid profile, blood pressure, and body fat distribution in type 2 diabetes.²⁵⁰ Regular exercise can potentially diminish the risk for atherosclerotic macrovascular disease in type 2 diabetic patients, as it does in the general population. Hyperinsulinemia, insulin resistance, and/or increases in intra-abdominal adipose mass (central obesity) are related to a high risk of atherosclerosis in type 2 diabetes. The basis for the effect of exercise may be its ability to diminish or prevent these risk factors.²⁵¹ Cardiovascular benefits of exercise are best achieved by aerobic exercise that improves maximal aerobic work capacity, ($\dot{V}O_{2\max}$) by both enhanced cardiopulmonary function and increased oxidative metabolism in the muscle.¹⁷²

Atherosclerotic vascular complications, affecting arteries in the heart, brain, and extremities, account for most morbidity and mortality in type 2 diabetic patients. Epidemiologic data and animal studies all indicate that physical training might retard atherosclerotic vascular disease in the general population although hard epidemiologic data are still lacking.²⁵¹ The incidence of fatal myocardial infarction among persons who exercised regularly for more than 10 years could be reduced by one-half in comparison with the sedentary controls, independent of other known risk factors including hypertension, cigarette smoking, and hypercholesterolemia.

It was shown that in type 2 diabetes, training can affect a number of parameters related to blood coagulation, but it is too early to indicate whether or not this represents an antiatherogenic effect of exercise. In the untrained state, fibrinolytic activity was impaired in diabetics and resting levels of plasma fibrinogen and the prothrombin time (PT) were increased. Activation of fibrinolysis occurred following exercise in both groups but the increment was less in pa-

tients with diabetes. Physical training could improve the resting and postexercise activated partial thromplastin time (APTT), VO_2max , and resting fibrinolytic activity in diabetics, in association with improved glycemic control.²⁵² Hyperlipidemia and disorders in lipoprotein metabolism are major risk factors for cardiovascular disease and occur with higher frequency in both type 1 and 2 diabetes. There is an increased prevalence of hyperlipidemia and diminished high-density lipoprotein (HDL) cholesterol in diabetics, presumably a function of metabolic control. Recent studies in type 1 diabetes²³³ show that intensive training increases the ratio of HDL cholesterol to total cholesterol. Training can reduce triglyceride levels in type 2 diabetes, an effect that appears to be rapidly reversed by inactivity. Hypertension markedly increases the frequency of vascular disease and occurs with greater frequency in patients with diabetes than in normal subjects. It is now recognized that essential hypertension is associated with insulin resistance and hyperinsulinemia, even in the absence of diabetes and obesity. In general, active individuals have lower systolic and diastolic blood pressure than sedentary control individuals matched for age.²⁵¹

SUMMARY AND SOME PRACTICAL RECOMMENDATIONS

The sedentary and over nourished lifestyle in nearly two-thirds of the population in modern society plays a critical part in the twentieth century "epidemic" of coronary heart disease. Physical activity and fitness are key determinants of whole-body or total health, that is, physical, social, cultural, and spiritual well-being. Inspired by the desire of diabetic patients to participate in various physical activities, sports, and games, there is a drastic increase in the number of publications related to sports activities for people with diabetes.^{161,172,251}

With the discovery of insulin, Joslin recommended that diet, insulin, and exercise represent the management triad in diabetes. The importance of exercise and general considerations with respect to exercise and diabetes have been reviewed and detailed plans for specific exercise prescriptions have been discussed.²⁵¹

Exercise cannot be regarded as an isolated, separate therapy but must be incorporated into the total program of treatment, including medication and diet. While most experts recommend aerobic exercise for improving insulin sensitivity and carbohydrate metabolism, some researchers suggest that some patients might benefit from resistance training. Some very general guidelines are recommended:

1. Before prescribing an exercise program, perform a complete history and physical examination. Evaluate diabetes control and complications.
2. Prescribe a moderate work load that is enjoyable and can increase slowly. Lifting and strong resistance training should be avoided.
3. Encourage self-managed blood glucose monitoring to document glycemic responses to various exercise modalities.
4. Encourage patients to schedule exercise to reduce postprandial hyperglycemia and discourage exercise during insulin action peak.
5. Exercising extremities should not be used as insulin injection sites.
6. Alert patients about the possibility of delayed exercise-induced hypoglycemia. Always have carbohydrate liquid handy.

7. Individuals who have been sedentary for years should begin exercising with a warm-up and proceed gradually to vigorous preferably aerobic activity and conclude with a cool-down period.
8. Patients with evidence of peripheral neuropathy should stay away from running and sports involving pounding of the low extremities that are likely to produce chafing and blister. Bicycling and swimming are ideal for most patients with diabetes.
9. Be aware of the potential problems of combining exercise with a diet that is deficient in calories or essential nutrients. Diet containing low calories and low carbohydrates can increase risks of cardiac arrhythmia, ketosis, and sudden death.

In conclusion, significant medical, physical, and psychological benefits of exercise can and should be achieved in most patients with diabetes. Appropriate planning will optimize these benefits and minimize potential complications and risks.

Ronald E. Chance

INTRODUCTION

In the early 1920s, Banting and Best¹ demonstrated the blood glucose lowering effect of pancreatic extracts and discovered a method for treating diabetes mellitus using an exogenous source of insulin. Since this breakthrough discovery, the intense focus on insulin research has produced extensive knowledge about the hormone's three-dimensional structural properties (see Chaps. 3 and 5),² its biosynthesis at the molecular and cellular level,^{3,4} and its biologic and physiologic effects.⁵ Despite the current understanding of insulin biochemistry, subcutaneous injection therapy remains the predominant method for effectively treating the more severe type 1 form of diabetes mellitus (T1DM). Therefore additional research efforts have been directed toward improving the overall effectiveness of insulin treatment, the goal being to mimic as closely as possible insulin secretion patterns in normal individuals. Frequently, this more practical emphasis on enhancing drug therapy has been directly influenced by discoveries made from more fundamental scientific explorations.

The chronology of the major achievements forming the basis of modern diabetes treatment have been discussed in previous reviews.^{6,7} In the area of pharmaceutical formulation, significant developments have been made involving the optimization of excipients, improvements in insulin purity, and the nearly total replacement of animal insulins with both recombinant human insulin and recombinant human insulin analogs. Consequently, insulin therapy has evolved from the early crude solutions of pancreatic insulin to a series of pharmaceutical preparations with short-, intermediate-, and long-acting profiles. Although the invention of the longer-acting, insoluble depot insulin preparations in the 1930s (protamine zinc insulin), the 1940s (NPH insulin), and the 1950s (zinc insulins) gave patients some reprieve from multiple daily injections of soluble insulin, for the most part these insulin formulations have not adequately mimicked normal insulin secretion, and thus have not provided optimal glycemic control.⁸ The large intra- and intersubject variability of absorption from the subcutaneous injection site is another major problem associated with current insulin preparations. Various approaches have been proposed in an effort to optimize insulin therapy using the available insulin preparations, involving multiple injection regimens,⁹ continuous subcutaneous insulin infusion (CSII),¹⁰ and delivery devices.¹¹ Alternative modes and routes of

delivery for insulin and other therapeutic agents have also been investigated.¹²

Large-scale, controlled multicenter clinical trials such as Diabetes Control and Complications Trial (DCCT)¹³ have provided conclusive evidence that effective blood glucose control using intensive insulin therapy reduces the development and progression of long-term microvascular and neurologic complications of T1DM. Normalization of plasma glucose concentration and duplication of the physiologic plasma insulin secretion pattern with elevations associated with meal consumption and a low concentration during fasting. The intensive injection therapy required to achieve normoglycemia is very demanding and imposes rigid constraints on the life style of the patient, and also presents an increased risk of severe hypoglycemia. There is optimism that new human insulin analogs recently approved will at least partially overcome the many inadequacies of older, traditional insulins. Clinical experience to date suggests these new analogs (insulin lispro and insulin aspart, both very rapid-acting, soluble, meal-time insulins; and insulin glargine, a soluble, basal insulin) display more desirable pharmacokinetic and glucodynamic behavior than the older insulins.¹⁴

The previous approaches to optimize insulin preparations have not been directed towards the intrinsic physicochemical properties of the insulin molecule. In particular, the potential role of insulin self-association on absorption was not considered, largely because detailed molecular information was lacking and conventional methodology to manipulate the primary structure was limited. Achievements derived from basic biochemical research on insulin have changed the current thinking about the nature of insulin preparations. High-resolution x-ray crystallographic data² and advances in molecular biology¹⁵ provided both the insight and the ability to explore the impact of insulin self-association on pharmacokinetic properties. The crystal structure of insulin provided a detailed understanding of the amino acids and molecular interactions involved in insulin self-association. Recombinant DNA technology made it possible to specifically modify any amino acid in the native sequence of insulin without having to rely on chemical modification or semisynthetic methods that are generally site-restricted.¹⁶ Optimization approaches based on a rational design of the insulin molecule became possible.

In this chapter, the various molecular modifications resulting in insulin analogs displaying altered pharmacological properties

reviewed. Specific emphasis is placed on analogs with amino acid modifications that disrupt insulin self-association. Research in this area has resulted in the creation of "monomeric" insulin analogs that are formulated as solution preparations and display more desirable pharmacokinetic profiles to cover meal-related insulin requirements. Efforts to modify the self-association of insulin to produce basal therapies have been more challenging. In this case, other design strategies to manipulate the properties of insulin have been employed.

For example, insulin glargine's basal action results from low solubility at physiologic pH due to a shift of the isoelectric point to near neutrality. The physicochemical properties of insulin and the formulation and pharmacologic aspects of conventional insulin preparations are also discussed to provide the necessary background information and the basis for application of rational design-based drug regimens for modern insulin treatment.

PHYSICOCHEMICAL PROPERTIES OF NATIVE INSULIN

The primary structure of insulin was determined by the pioneering work of Sanger and colleagues at Cambridge University beginning in the late 1940s and culminating with the elucidation of amino acid sequences for several mammalian insulins in the 1950s.¹⁷ Insulin is a 5800-Dalton-molecular-weight protein having 51 amino acids and consisting of two polypeptide chains designated the A chain and the B chain (Fig. 28-1). The A chain contains 21 amino acids, while the longer B chain is composed of 30 residues. Two intermolecular disulfide bonds involving cysteine residues A7,B7 and A20,B19 connect the individual chains. There is one additional intramolecular disulfide bond in the A-chain sequence between cysteine residues at positions A6 and A11. Putative residues involved with receptor interactions have been deduced from studies involving modification of selected residues.¹⁸

Much of the structural knowledge of insulin has been derived from studies conducted on bovine and porcine insulins. Bovine insulin differs from the human sequence at two positions in the A chain, in which alanine replaces threonine at position A8 and valine substitutes for isoleucine at residue A10. The B chain of bovine insulin additionally differs at position B30, where threonine is replaced by alanine. A similar alanine substitution at position B30 occurs in porcine insulin, and is the only difference relative to the human sequence. These sequence differences are not thought to affect the structural aspects or ligand binding properties of the three wild-type insulins. Today, the primary structures for more than 100 species of insulin and related molecules are known. Considering all the species of insulin and the various insulin analogs synthesized for structure and activity studies, more than 1000 molecules have likely been studied in insulin chemistry laboratories throughout the world [personal communication with J.E. Shields].

Structure of the Monomer

At dilute solution concentrations ($<0.1 \mu\text{M}$, $\sim 0.6 \mu\text{g/mL}$), insulin exists as a monomer. Insulin circulates in plasma as a monomer,¹⁹ and it is this form that interacts with the receptor.⁴ X-ray crystallographic studies suggest that the three-dimensional structure of the monomer is not substantially altered upon self-association to the dimer and the hexamer.²⁰ The tertiary structure of the insulin monomer derived from x-ray crystallography² (Fig. 28-2A) indicates that the A chain consists of two α -helical segments involving residues A1–A8 and A13–A19, that are connected by a short loop from A9 to A12. The remaining two C-terminal residues are in an extended conformation. Structural elements of the B chain consist of a straight chain at the N-terminus (B1–B8) followed by an α helix (B9–B19) and ending with a long β strand (B20–B30) at the C terminal end. There is extensive conformational flexibility in the N-terminal region of the B chain, such that binding of certain ligands to insulin hexamers can induce an α -helix structure involv-

FIGURE 28-1. Primary structure of human insulin with amino acid residues involved in dimer formation shown in black and those involved in assembly of the Zn^{2+} -insulin hexamer in gray. The arrows indicate putative sites involved in receptor interactions. (Reproduced with permission from Brange et al.⁸⁰)

ing residues B1–B8 in the monomer subunits.²¹ This structural transition is discussed further in the section on self-association and ligand binding.

The solution state conformation of the insulin monomer has been examined by several experimental and theoretical techniques including NMR,²² circular dichroism,²³ competitive labeling of functional groups,²⁴ and molecular dynamics simulations.²⁵ In contrast to x-ray crystallography data, the results of some of these studies suggest that there are conformational differences between the free and associated insulin monomer. While the significance of the purported differences is still not entirely understood, the results of other studies suggest that conformational flexibility in the insulin monomer is necessary for receptor interactions.²⁶

High-resolution (500 MHz), ¹H Fourier transform nuclear magnetic resonance (NMR) imaging conducted on dilute solutions of insulin at pH 8.0 (pH electrode reading) and higher has allowed the spectrum of the native insulin monomer to be obtained.²² Spectral changes observed under conditions at which the dimer predominates were interpreted as differences between the monomer conformation in the free and associated states. A vacuum ultraviolet (UV) circular dichroism study exploring the changes in secondary structure associated with the dissociation of insulin hexamers also revealed structural differences between the free and associated monomers.²³

Insulin Self-Association and Ligand Binding

The self-association of insulin has important implications in *in vivo* processes⁴ and in pharmaceutical formulation.²⁷ Insulin association has been studied in solution with several elegant physical chemistry methods as reviewed recently by DeFelippis and colleagues.²⁸ These include ultracentrifugation, light scattering, equilibrium dialysis, difference UV absorbance spectroscopy, stopped-flow kinetics, osmometry, circular dichroism spectroscopy, and NMR. In the absence of divalent metal ions, insulin exhibits a complex association pattern consisting of monomer, dimer, tetramer, hexamer, and higher-order species, all in dynamic equilibrium and further influenced by protein concentration, pH, ionic strength, and temperature. Multiple models have been used to describe insulin self-assembly; however, it is clear that dimer formation is a necessary prerequisite for higher order aggregation.²⁹ Metal ions such as zinc will shift the equilibrium towards the formation of insulin hexamers.³⁰

X-ray crystallography has provided the most detailed information concerning the interactions involved in insulin self-association.² The predominant forces resulting in dimer formation are nonpolar interactions and hydrogen bonds. With the exception of the asparagine residue at position A21 (a highly conserved amino acid among insulin species), the amino acids involved in dimer formation are all located in the B chain (Fig. 28-1). Most of the nonpolar interactions occur in the extended, C-terminal region of the B chain involving residues B23–26 and B28. A short, antiparallel β sheet with hydrogen bonds involving residues B24 and B26 also secures the C-terminal B chains of adjoining monomers (Fig. 28-2B). The importance of the C-terminal B chain residues in monomer-monomer association is demonstrated by despentapeptide insulin (lacking residues B26–B30).^{20,31}

The divalent metal ion binding capacity of insulin was first demonstrated by Scott,³² and the presence of zinc is known to cause specific aggregation to hexamers. Hexamer formation is strongly pH-dependent, occurring when the molar ratio of zinc to

insulin is between 0.33 and 1.0 and the protein concentration above 0.5 mg/mL.^{30,33} Note that these conditions are achieved commercial solution preparations of insulin. A value of 10^{11} M has been reported for the dimer-hexamer association constant zinc-containing porcine insulin.^{33,34} Two classes of zinc binding sites have been identified in the insulin hexamer. The stronger zinc binding site has an apparent association constant of 10^5 – 10^6 M while the weaker one is in the range of 10^3 – 10^4 M⁻¹.²⁹ The insulin hexamer is capable of binding additional zinc ions.³⁵ Multiple weak zinc-binding sites involving interactions with carboxyl groups have also been observed by x-ray crystallography studies on zinc-soaked crystals.³⁶

X-ray crystallography studies have led to the identification of three hexameric insulin structures designated 2-Zn, 4-Zn, and 6-Zn phenol-induced species.^{2,21,37} The naming convention originally based on analytically-determined zinc content³⁵ leads to confusion since the 2-Zn form can bind more than two zinc ions³⁶ and the 4-Zn hexamer does not bind four zinc ions in all examples studied.³⁷ Therefore, the three structures are more appropriately defined in accordance with allosteric nomenclature as T₆, T₃R₃, and R₆, respectively.³⁸ The T and R designations refer to the conformational transitions associated with the B1–B8 residues in the insulin monomer subunits of the hexamers (Fig. 28-2D). Regardless of these structural differences, all three hexamer forms are observed as spheroidal assemblies having a diameter of ~5 nm and a height of ~3.5 nm.

Evidence for the existence of the various hexamer forms in solution has been obtained using circular dichroism,³⁹ UV-visible absorption spectroscopy,^{38,40,41} and NMR.⁴² Direct evidence for the existence of a solution state R₆ hexamer structure has been recently obtained by ¹H-NMR.⁴² The exceptional thermal stability of this hexamer form allowed high-resolution NMR spectra to be obtained, demonstrating an overall similarity between the secondary, tertiary, and quaternary structure between solution and crystal structures. Furthermore, the distinctive secondary structural features of the N terminus of the B chain were observed. Of the three hexamer structures, the R₆ species is particularly relevant to pharmaceutical solution preparations of insulin, since phenolic excipients are added as antimicrobial agents. The other structures, specifically the T₆ form, may be associated with the events controlling hexamer dissociation at the subcutaneous injection depot.

In the T₆ insulin structure, three dimers are assembled around two centrally-located zinc ions positioned in a solvent-filled cavity running through the hexamer (Fig. 28-2C). Each of the zinc ions is coordinated to three histidine B10 side chains, one from each dimer and three water molecules in an octahedral arrangement.² At the center of the hexamer, six glutamic acid B13 residues are arranged in a circular pattern, and the charge repulsion caused by the close proximity of the normally ionized carboxyl side chains necessitates zinc binding to stabilize hexamers. This fact is emphasized by substitution of the glutamic acid residue at position B13 with glutamine, resulting in an insulin analog capable of forming stable, zinc-free hexamers.⁴³ Assembly of the hexamer causes both polar and nonpolar residues to be buried between dimers, although the packing is much looser than in the interface between monomers comprising the dimer. The six monomer subunits of the T₆ insulin hexamer all have B1–B8 residues in an extended conformation while the B9–B19 regions are α -helical.

Crystallization of insulin conducted in the presence of high concentrations of lyotropic anions such as chloride ion or thiocyanate results in the T₃R₃ hexamer.^{37,44} Note that lyotropic

anions cannot drive the T $\rightarrow$ R transition to completion. In three of the monomer subunits, the N-terminal B1–B8 residues adopt an α -helical conformation producing a continuous α helix from B1–B19, while the monomers in the other half of the hexamer all have an extended chain in this region (Fig. 28-2D). This conformational transition displaces the N terminus of the B chain by more than 30 Å, producing three symmetry-equivalent cavities in the vicinity of the B5 histidine residues. X-ray crystallographic studies indicate that these cavities are either fully or partially occupied by zinc ions coordinated in a tetrahedral geometry involving the side chain of histidine B5, the side chain of histidine B10 positioned in an orientation off the 3-fold axis, and two water molecules.³⁷ A zinc ion can also be coordinated on the 3-fold axis by another orientation of the three symmetry-related histidine B10 side chains and a chloride ion in a tetrahedral geometry.³⁷ The other zinc ion in the T-state trimer is octahedrally coordinated by three symmetry-related B10 histidine residues and three water molecules, similar to the geometry observed in the T₆ insulin hexamer.³⁷

More recent x-ray crystallographic studies on the T₃R₃ human insulin hexamer have shown that the putative off-axial zinc binding sites do not contain zinc ions, but rather are filled with water molecules.⁴⁵ In addition, both of the axial zinc ions exhibit a dual coordination pattern with no evidence for a second orientation of the B10 histidine residue. Most notably, the T $\rightarrow$ R transition in the R-state trimer results in the formation of a 12-Å-deep channel. The zinc ion lies at the bottom of this channel, isolated from the environment.⁴⁵ These authors suggest that zinc dissociation from the hexamer requires conversion of the R-state trimer to the T conformation, allowing solvent access to the metal site. They also observed that the first three N-terminal B-chain residues were extended rather than α -helical in the R-state monomer subunits. The term R^f is now used to distinguish the B1–B3 “frayed” conformation from the fully α -helical R form (see Fig. 28-2D), and the hexamer conformation is referred to as T₃R₃.^{44,46,47}

Some phenolic molecules that are used as antimicrobial agents in pharmaceutical preparations have been shown to bind the insulin hexamer.^{21,48} In this hexamer structure, referred to as R₆, the N-terminal B1–B8 residues of all six monomer subunits are α helical, producing a continuous helix from B1–B19. There are two off-axis binding sites at each dimer-dimer interface, and each position contains one phenol molecule. Each phenol molecule donates a hydrogen bond to the A6 cysteine carbonyl oxygen and accepts a hydrogen bond from the A11 cysteine amide nitrogen.²¹ The phenol molecules are located in a cavity formed by A-chain residues of one dimer and the B1–B8 helix from an adjacent dimer. This arrangement allows the histidine B5 residue to link the dimer through van der Waals contacts with the phenol molecule. There are two zinc ions located on the hexamer 3-fold axis, both of which are coordinated in a tetrahedral arrangement involving the three

B10 histidine side chains and a chloride ion. The α -helix extended above the zinc binding sites, limiting accessibility of the metal ions.³⁸

INSULIN SECRETION IN NORMAL INDIVIDUALS

Insulin is matured from preproinsulin and proinsulin, stored and secreted by the β cells of the islets of Langerhans in the pancreas (see Chaps. 3 and 4). The biochemical events associated with these processes and corresponding structural transformations of the insulin molecule are now becoming understood in great detail. In the storage vesicles, insulin hexamers form microcrystals that apparently serve to protect the hormone from proteolytic degradation. Upon release into serum, the insulin microcrystals experience a change in pH ($\approx$ 5.5 to 7.4) destabilizing favorable hexamer interactions. Dilution of the zinc ions also occurs, causing rapid hexamer dissociation and crystal disintegration. Secreted insulin enters the portal vein and is delivered directly to the liver, where a half is removed by first-pass metabolism. The concentration of insulin in the blood is 10^{-8} – 10^{-11} M, ensuring that the hormone circulates and interacts with its receptor as a monomer.^{19,33}

Studies conducted in normal subjects have defined the physiological secretion profile in response to various test meals over a course of 24 hours (Fig. 28-3).^{6,49,50} The insulin secretion profile is pulsatile and displays both stimulated and basal phases. In the stimulated phase, increases in serum insulin may reach levels of 60–80 μ U/mL or more within a few minutes before declining to basal levels (5–15 μ U/mL) within 120–180 minutes. These elevations in insulin result in disposal of glucose and other nutrients into the peripheral tissues, principally muscle tissue and to a lesser extent into the liver and fat. Between meals and through the night, low levels of insulin are secreted at approximately 1 unit per hour (note that an international unit of insulin is equal to $\sim$ 35 μ U). Basal insulin secretion restrains but does not totally inhibit hepatic glucose production, assuring adequate substrate for cerebral glucose metabolism.⁶

INSULIN PREPARATIONS: PROPERTIES, PHARMACOLOGY, AND DEFICIENCIES

Pharmaceutical Preparations

Throughout the history of insulin, the desire to optimize subcutaneous injection therapy to more closely simulate the secretory patterns of normal persons has influenced the nature of the pharmaceutical preparations used for treatment. The most significant advances have occurred in the area of pharmaceutical formulation where excipients have been optimized and approaches defined

FIGURE 28-2. Insulin structure and pattern of self-association. Panel A shows the porcine insulin monomer structure with the A chain drawn using thin lines and the B chain drawn using thick lines. Panel B shows the antiparallel β sheet and hydrogen bonding structure within the insulin dimer. The pattern of insulin self-association from monomers to dimers and zinc-induced hexamers is depicted in panel C. Only backbone and selected side chains important to assembly are shown. The histidine residues at position B10 coordinate the two central zinc ions. The six B13 glutamic acid residues are buried in the hexamer. At neutral pH, the side chains of these residues are negatively charged, and these unfavorable interactions may play a role in hexamer dissociation upon removal of zinc ions. Insulin hexamers adopt various quaternary structures in the presence of certain anions or phenolic molecules. Conformational changes are localized to residues B1–B8 of monomer subunits. For ease of viewing, panel D only shows the conformation of insulin B chains in the T state, R state, and R^f state. (Panels A and B reproduced with permission from Baker et al.²; panel C reprinted with permission from Dodson and Steiner⁴; panel D reprinted with permission from Ciszak et al.⁴⁶)

FIGURE 28-3. Mean peripheral plasma insulin and glucose profiles in five normal subjects ingesting 630-kcal meals composed of 40% carbohydrate, 40% fat, and 20% protein. The meals took 15 minutes to ingest. All subjects were ambulatory but did not exercise. The plasma glucose concentration increased only 50% during the meals, whereas the plasma insulin concentration increased approximately 600%. The pattern of the rise in plasma insulin concentration closely matches that of the rise in plasma glucose concentration. (Reproduced with permission from Schade et al.⁴⁹)

alter pharmacokinetics. Several comprehensive reviews describe the various insulin preparations that have been available over the years.^{27,51,52} The specific developments leading to present day insulin preparations are briefly discussed here to provide the necessary background information relating to physical and pharmacologic properties.

Commercial insulin preparations are generally classified depending upon duration of activity as rapid-acting (reaching peak insulin concentrations from approximately 1–3 hours following subcutaneous injection, with a maximum duration of action of 4–6 hours), intermediate-acting (reaching peak insulin concentration at approximately 4–12 hours following subcutaneous injection, with a maximum duration of action of 14–20 hours), or long-acting (minimal peak with a maximum duration of action of 20–30 hours). Rapid-acting preparations are solutions of insulin, while intermediate- and long-acting preparations are composed of amorphous and/or crystalline insulin particles.

Formulation Properties

The earliest insulin preparations were slightly irritating, acidic solutions containing impure insulin isolated from animal pancreata. Because of the low purity of these preparations, patients typically required 4–6 daily injections. A neutral pH, solution preparation of insulin containing NaCl as a tonicity modifier and the preservative methylparaben was not developed until the 1960s.⁵³ Current, commercially available rapid-acting human insulin preparations are most commonly unbuffered, neutral pH solutions manufactured in 100 U/mL (approximately 3.5 mg/mL insulin) with some 40 U/mL (approximately 1.4 mg/mL insulin) strengths. Alternatively, a phosphate buffer (neutral pH) is included specifically for insulin solutions formulated for use with pump devices. Other excipients included in these preparations include Zn^{2+} ions and glycerin as a tonicity modifier. A phenolic preservative, such as m-cresol at a concentration of about 3 mg/mL, is also included to satisfy stringent antimicrobial effectiveness regulatory requirements for multi-

dose parenteral products. The significance of formulation ingredients was not fully appreciated prior to the attainment of a detailed understanding of insulin structure, self-assembly, and phenolic ligand binding propensity. Due to the concentrations of insulin, zinc ions, and phenolic preservative in these preparations, the R_6 hexameric form of insulin likely predominates in solution.

The limited duration of action of the early insulin preparations required inconvenient multiple dosing regimens and carried the risk of overnight hyperglycemia. These deficiencies led to the development of modified formulations with prolonged action, so injection frequency could be reduced and insulin activity maintained through the night. The first successful extended-acting preparation utilized protamine to precipitate insulin as a noncovalent complex.^{54,55} Protamine is a highly charged ($pI \sim 13.5$), basic peptide consisting of about 30 amino acid residues⁵⁶ generally isolated from salmon sperm. Krayenbühl and Rosenberg⁵⁷ optimized the insulin-protamine formulation by devising the isophane method for producing a microcrystalline suspension buffered at a neutral pH known as NPH (Neutral Protamine Hagedorn). The term isophane refers to the proper stoichiometric proportions of insulin and protamine (approximately 12:1 on a weight basis) that are used in the process, such that formation of the crystalline complex results in essentially no free amounts of either species in solution. Phenolics, such as m-cresol and phenol, and Zn^{2+} ions are also required to produce the elongated, tetragonal crystals comprising the suspension. The phenolics also serve a dual role as antimicrobial agents. NPH insulin has an intermediate time action and presently remains the most widely used insulin preparation.

After the introduction of NPH, another method for producing extended-acting insulin without the use of protamine was discovered by Hallas-Møller, Petersen, and Schlichtkrull,⁵⁸ who determined that the addition of excess zinc ions to formulations having neutral pH and no phosphate buffer produced suspensions displaying protracted effects. The prolonged effect is a result of the molar excess of Zn^{2+} ions that substantially reduces insulin solubility at neutral pH conditions. This finding led to the development of Lente insulins, a series of three suspension preparations having a gradation of extended activity. Semilente, a suspension composed entirely of amorphous particles formed by adjustment of an acidic insulin solution containing excess zinc ions to neutral pH, displays only a moderately retarded effect. Controlled crystallization of insulin at pH 5.5 in the presence of excess zinc ions, high NaCl concentration, and insulin seed crystals results in the formation of rhombohedral insulin crystals of uniform particle size distribution. The entirely crystalline Ultralente suspension is then prepared by diluting these crystals with an aqueous vehicle containing methylparaben and a controlled Zn^{2+} ion concentration followed by adjustment to neutral pH. Ultralente insulin was the longest-acting insulin suspension formulation currently available commercially until the recent development of glargine. Lente insulin is a 3:7 mixture of amorphous and crystalline insulin particles having an intermediate time-action profile. The crystalline component is the Ultralente crystal form while the amorphous part is analogous to Semilente.

Because of the small size and poor crystal quality of Ultralente particles, structural characterization by x-ray crystallography has not been possible. Recent powder diffraction studies on Ultralente crystals have identified the T_6 hexamer conformation.⁵⁹ In contrast to these findings, previous x-ray crystallography results on 4-Zn insulin crystals presumed to be representative of the Ultralente suspension identified the T_3R_3 hexamer conformation.³⁷ As a possible

explanation for the extended activity of Ultralente preparations, these authors proposed that conversion of the R-state trimer to the T conformation was required to allow solvent access to the metal site prior to dissociation of the hexamers. However, the recent powder diffraction results indicate T_6 hexamers are more consistent with the actual concentration of sodium chloride used in the Ultralente preparation. Therefore, the time action is unlikely to be influenced by a mechanism involving the $R \rightarrow T$ conversion. Ultralente crystals contain T_3R_3 hexamers when they are initially grown under high sodium chloride conditions, but the conformation converts to the T_6 form when the salt concentration is diluted for the commercial product.⁵⁹

One of the more recent advances in insulin formulation involves the development of stable mixtures containing rapid- and intermediate-acting insulins. These preparations combine insulin solutions with NPH suspension in various mixture ratios including 10:90, 20:80, 30:70, 40:60, and 50:50 (the 30:70 and 50:50 preparations are available in the U.S.). The basis for such premixed insulins is the convenience of having both meal-related and basal insulin requirements available in a single injection. In addition, the preparations offer better accuracy over extemporaneous mixtures made by the patient. Indeed, one of the most common subcutaneous injection regimens involves twice-daily injections of rapid- and long-acting insulins, making these preparations very popular.⁶⁰ A certain portion of the soluble component in these mixtures is known to adsorb to the surface of the NPH crystals.^{27,61} However, this predominantly electrostatic interaction is reversible and does not alter the time action of the soluble component.⁶¹ In contrast to the regular/NPH mixtures, combinations of rapid-acting insulin with Ultralente do not have sufficient long-term stability to allow a premixed preparation. The excess zinc present in Ultralente will precipitate the rapid-acting insulin, retarding its onset of action.⁶² However, the combination of rapid-acting insulin and Ultralente can be utilized immediately after mixing.

Insulin Purity

Improvements in the overall purity of insulin preparations were first achieved by application of crystallization procedures, most notably those conducted in the presence of Zn^{2+} ions in addition to recrystallization methods. For many years, multiply-recrystallized insulin was thought to be very pure because preparations manufactured in this manner were found to be better tolerated by patients prone to allergic reactions.²⁷ As advances in analytical methodology progressed and techniques such as polyacrylamide gel electrophoresis and size exclusion chromatography were applied to examine insulin,^{63,64} recrystallized insulin was found to contain numerous proinsulin- and insulin-like substances in addition to several noninsulin peptides (e.g., glucagon and pancreatic polypeptide).^{27,65} This observation led to the incorporation of chromatographic separation technologies into the purification processes to produce so called single- or mono-component insulin.^{65,66} Insulin preparations manufactured with chromatographically-purified insulin helped to reduce the frequency of immunologic complications associated with the therapy, such as allergy, lipatrophy, and resistance. The subsequent introduction of recombinant human insulin, which is considered to be less immunogenic than either the porcine or bovine forms, further improved the immunologic consequences of diabetes treatment, since insulin antibodies may influence insulin pharmacokinetics.⁶⁷ The immunogenic and allergenic aspects associated with insulin therapy have been reviewed elsewhere.⁶⁸

Insulin Sources

Prior to the early 1980s, all commercially available insulin preparations were formulated with either bovine or porcine insulin or a mixture of the two. The complete chemical synthesis of insulin was demonstrated in the 1960s,^{69–71} but the inefficiency and yields of such a process make it impractical for commercial manufacture of human insulin. A human insulin for use in commercial pharmaceutical preparations was later developed using a synthetic process whereby the alanine at position B30 of porcine insulin was exchanged for threonine using a combination of chemical and chemical processes.^{72,73}

Advances in recombinant DNA technology, demonstrating the ability to express synthetic genes for the A and B chains of human insulin eventually provided a method for producing human insulin biosynthetically.¹⁵ The first biosynthetically manufactured human insulin to receive regulatory approval was prepared by expressing the chemically synthesized genes for the two chains of insulin in *Escherichia coli*.^{74,75} This biosynthetic process later was modified to include the initial production of proinsulin that was subsequently converted to human insulin by enzymatic and chemical methods.^{76,77} An alternative biosynthetic manufacturing process currently used for commercial human insulin production involves the expression in *Saccharomyces cerevisiae* of a single-chain insulin precursor containing a short amino acid sequence linking the A and B chains.⁷⁸ Additional enzymatic and chemical processes complete the conversion to human insulin.

There is some evidence from clinical studies that human insulin preparations are absorbed more rapidly than porcine insulin preparations, although the basis for this difference is not clearly understood. X-ray crystallography studies comparing human and porcine insulin have identified significant shifts in the main chain atoms of B30 at the carboxyl groups and some additional changes in the solvent structure in the region of B28–B30.⁷⁹ This difference may account for the greater hydrophilicity of human insulin crystals, suggesting that slightly increased solubility is a possible explanation for the faster absorption of the microcrystalline suspension preparations. Brange and associates⁸⁰ have proposed that small differences in absorption of regular human insulin relative to soluble porcine insulin preparations can be explained by a greater tendency towards dissociation observed in their studies. Based on the x-ray crystallography results, Chawdhury and coworkers⁷⁹ suggest that the threonine residue at position B30 in human insulin and the associated structural alterations it causes affect the strength with which dimers are held together within the hexamer. However, the clinical significance of the differences in absorption between human and porcine insulin is debatable.⁸¹ As discussed below, the faster absorption rate for soluble preparations is not necessarily a disadvantage for meal-related insulin requirements, although regular human insulin is not nearly rapid enough to mimic the physiological secretion profile (e.g., see Fig. 28-4). On the other hand, rapid absorption is generally considered undesirable in terms of basal insulin needs.⁸²

Pharmacology of Insulin Preparations

The pharmacologic profiles of the various insulin preparations administered subcutaneously have been reported by numerous investigators.^{80,82–92} These studies provide a means for evaluating how well the various insulin preparations simulate physiologic secretion patterns and glucodynamics of insulin. Heinemann and Richter⁸² have emphasized that many investigations on insulin

FIGURE 28-4. A comparison of the glucodynamic response of 10 normal volunteers to subcutaneous or intravenous administration of Humulin® R (0.2 U/kg). Glucose consumption was assessed using the glucose clamp technique. Note that the peak effect following subcutaneous administration occurs between 3 and 4 hours and continues for at least 8 hours. (Reprinted with permission from Galloway et al.⁹³)

absorption (pharmacokinetics) and/or insulin action (pharmacodynamics) have involved inappropriate methods and different doses and sites of administration, making it difficult to compare results. Therefore our intent is to provide a general description of the pharmacologic profiles of each insulin preparation rather than a comprehensive examination of all the data on this topic. Of the various methods used to study the pharmacologic properties of insulin preparations, the euglycemic glucose clamp is considered the most ideal for determining pharmacodynamics and pharmacokinetics.⁸² The euglycemic glucose clamp procedure involves intravenous glucose infusion to maintain blood glucose concentrations at normal values following administration of insulin. The glucose requirement, therefore, is proportional to the activity of insulin.

Pharmacokinetics and Pharmacodynamics

Prandial (Meal-Related) Insulin

An example of the time course of plasma glucose response in normal subjects following subcutaneous administration of a commercially available solution preparation of regular human insulin (Humulin® R) is illustrated in Fig. 28-4. There is an obvious difference between this profile and the profile for intravenous administration, which better simulates physiologic insulin secretion. First, the rate of glucose consumption is slow, indicating that the plasma insulin concentration does not peak rapidly. Second, there is no real peak in the profile, and the maximal response does not occur until almost 3 hours after injection. Finally, glucose infusion is still required to maintain euglycemia even 8 hours after administration, indicating that plasma insulin concentrations are not rapidly reduced. This glucodynamic profile indicates a situation of relative hypoinsulinemia during the early phase (0.5–3 hours) following injection and relative hyperinsulinemia at later stages (3–8 hours). As a consequence of these abnormal conditions, the early-stage postprandial insulin deficiency causes delayed suppression of endogenous glucose production by the liver and a below-normal increase in the rate of glucose uptake by peripheral tissues, resulting in hyperglycemia soon after meal ingestion. Additionally, the elevated plasma insulin concentration that extends beyond 3 hours after the

meal may lead to conditions of hypoglycemia. Therefore, the pharmacologic properties of regular soluble insulin are more consistent with an intermediate-acting preparation.^{6,14,93} In contrast to the profile obtained following subcutaneous injection of regular insulin, intravenous administration better simulates a meal-stimulated secretion pattern.^{6,93} As mentioned below, two new soluble insulin analogs have been developed (insulin lispro and insulin aspart) that are quicker-acting with a shorter duration of action than regular human insulins.

Basal Insulins

Another requirement for achieving glycemic control is effective suppression of hepatic glucose production. Normalization of hepatic glucose production can be achieved by simulating the postabsorptive, low levels (5–12 μ U/mL) of insulin secretion that occur in healthy nondiabetic individuals. There presently are two approaches in use for satisfying basal insulin requirements, either continuous subcutaneous insulin infusion (CSII) or subcutaneous injection of NPH, Lente, Ultralente, or preferably insulin glargine preparations. For the purposes of this discussion, only the pharmacologic properties of the subcutaneous microcrystalline suspensions are considered. The topic of CSII has been addressed in other reviews (see Chap. 29).⁹⁴

A euglycemic clamp study in normal persons compared the time-action profiles of four widely used NPH insulin preparations.⁸⁹ This study showed that the onset of action (defined as half-maximal action) of all the NPH preparations was within 2.5–3 hours (Fig. 28-5). Peak activity was attained after 5–7 hours, and the duration of action (defined as >25% of maximal action) was between 13 and 16 hours. Certain clinical studies have shown differences in the time-action profiles of NPH insulins prepared with human or porcine insulin.⁸² In these cases, human insulin NPH displays a more rapid onset and shorter duration of activity. In another euglycemic clamp study in normal subjects, human insulin NPH was found to be absorbed faster than a Lente preparation of human insulin over the course of 8 hours.⁸⁸ The peak effect and relatively short duration of activity associated with these intermediate-acting preparations make them ineffective as true basal insulins. Although the premixed NPH/regular insulin preparations are very popular in diabetes treatment, the limitations of their individual pharmacologic properties still exist.

The Ultralente insulin preparation is commonly used as a basal insulin. A euglycemic clamp study evaluating Ultralente preparations manufactured with insulin from either human, porcine, or bovine species have defined the time-action profile and uncovered some interesting differences.⁹⁰ Examples of the time-action profiles over the time course of 40 hours following administration of a 0.4 U/kg dose of each preparation are shown in Fig. 28-6. While all of the preparations displayed a duration of activity in excess of 30 hours, human Ultralente displayed plasma insulin levels in excess of 60 μ U/mL within 5 hours after injection that persisted for at least 30 hours. The time-action profile of human insulin Ultralente, therefore, is not consistent with a truly basal insulin. In contrast, bovine Ultralente displayed a flat, essentially peakless profile with serum insulin concentrations below 60 μ U/mL, although it was noted that a consistent peak was not evident in this case due to the wide variability between subjects. Based on the results of this study, it can be concluded that bovine Ultralente provides a more suitable basal insulin time-action profile. However, the undesirable immunogenicity of bovine insulin⁶⁸ limits its usefulness in this

FIGURE 28-5. Glucose infusion rates (bars), free plasma insulin, and C peptide concentrations after subcutaneous injection of 12 U of four different NPH insulin preparations (biosynthetic origin: Humulin N [A], Eli Lilly; semisynthetic origin: Insulatard® H [B] and Protaphane® HM [C], Novo/Nordisk; Basal-H® Insulin [D], Hoechst AG; all U40) at time 0 during 19-hour euglycemic glucose clamps in six normal subjects. Solid bars show basal glucose infusion rate. (Reproduced with permission from Starke et al.⁸⁹)

regard. Despite the differences in time-action between the various Ultralente insulins, the authors of this study ultimately concluded that any one of the preparations is suitable to provide basal insulinemia in clinical practice. Conflicting pharmacologic results from a variety of other studies provide no definitive answer to the question of whether the time-action profile of human insulin Ultralente is more consistent with an intermediate-acting rather than a long-acting preparation.⁸² Nevertheless, a twice-daily human insulin Ultralente injection regimen has been shown to result in lower fasting blood glucose concentrations.^{95,96}

The differences in the time-action profiles of bovine and human Ultralente may be related to solubility²⁷ or immunogenic potential.⁶⁸ In the latter case, insulin released from the crystals may bind to elevated levels of circulating antibodies, further delaying the absorption process. Recent atomic force microscopy studies have provided evidence suggesting that differences in time action between bovine Ultralente compared to either human or porcine Ultralente may be related to packing and orientation of insulin hexamers at the crystal-solution interface.⁹⁷ In bovine Ultralente crystals, the hexamers on the predominant faces [(010) and (110)] are oriented “edge-on” to the aqueous medium, limiting solvent penetration into the crystals and consequently further retarding dissolution. Conversely, the predominant exposed crystal surface of human and porcine Ultralente crystals is the (001) crystal plane.

Hexamer orientation on this face allows for easier penetration of solvent through the crystal surface, contributing to more rapid dissolution.

The development of an insulin formulation with the duration of action of bovine Ultralente insulin but without immunogenicity has been a goal of insulin researchers for many years. As described below, a new peakless soluble insulin (insulin glargine) with a long duration of action has recently been introduced that appears to fulfill the desired characteristics of such a basal insulin.

Injection Timing and Clinical Implications

Since it takes between 60 and 90 minutes for subcutaneously injected regular soluble insulin (e.g., Humulin R) to reach peak plasma levels, timing of the injection is critical. Prandial insulin should be administered at least 30 minutes before the meal, to account for the time lag before maximal activity. A number of clinical studies have demonstrated the importance of injection timing for regular insulins.^{98,99} The results of one study are presented in Fig. 28-7, which shows that the longer the interval between injection and meal ingestion, the better the simulation of nondiabetic prandial insulin secretion. There are also clinical implications for the long-acting insulin preparations. In clinical practice, injection timing with NPH and Lente insulin preparations is critical to ensuring that metabolic control is effectively maintained through the night.⁸²

FIGURE 28-6. The plasma insulin and glucodynamic response of 6 or 9 normal volunteers following the subcutaneous administration of placebo and Ultralente bovine, porcine, and human insulin, 0.4 U/kg. (Reproduced with permission from Seigler et al.⁹⁰)

Thus an evening dose of human insulin NPH is generally injected closer to bedtime. The duration of action of human insulin Ultralente is also not considered substantially longer than NPH, necessitating twice-daily injections of the preparation to achieve basal insulin requirements.⁸²

Factors Affecting the Absorption of Insulin

The factors influencing absorption of insulin from the subcutaneous site have been clinically examined, and the topic has been the subject of many reviews.^{62,80,85,100,101} These investigations have shown that the region of injection, blood flow, and technique of injection can all influence the absorption process. For example, absorption is faster from the abdominal as opposed to the deltoid, femoral, and gluteal regions. Absorption is also faster with deeper

injections, or if insulin is injected more slowly. As temperature will affect blood flow, increases due to exercise, fever, and massage will also cause faster absorption. Other miscellaneous factors resulting in faster absorption include a lower injection volume or concentration of insulin. The use of NPH instead of Lente insulin in a bolus/basal mixture will also impact absorption because the excess zinc in the Lente preparation will precipitate soluble insulin, causing a blunting of its effect.^{83,102}

While some of the factors influencing absorption described above can also impact insulin suspension preparations,¹⁰³⁻¹⁰⁵ it is reasonable to suggest that their protracted effects are a result of slow crystal dissolution at the injection site. In these cases, absorption of insulin into the bloodstream presumably can only occur once the hormone is freed from the crystals. This presumption is

FIGURE 28-7. Pre- and postprandial plasma glucose and insulin levels in 8 insulin-dependent diabetic subjects given 30-minute subcutaneous infusions of insulin beginning 60 minutes (open circles), 30 minutes (solid circles), and immediately before (solid squares) ingestion of a standard meal. The shaded area represents one standard deviation above and below the mean of observations in 8 normal individuals. (Reproduced with permission from Dimitriadis et al.⁹⁹)

substantiated by recent studies, in which monomeric analogs were formulated as either NPH or Ultralente suspensions without significantly altering the pharmacologic properties relative to corresponding human insulin preparations.^{59,106} What remains even more elusive is a detailed understanding of the molecular events following subcutaneous injection of regular insulin. In particular, what intrinsic properties of the hormone, if any, influence the absorption process? Greater insight into the subcutaneous absorption mechanism has recently been obtained by considering the potential relationship of insulin self-association to pharmacokinetics and pharmacodynamics^{80,107,108} as discussed in the following section.

A Model for Insulin Absorption: Implications of Self-Association

At the β -cell level, the propensity of insulin to self-associate into hexamers is crucial for the hormone's processing and storage.^{4,36} This property of insulin has been exploited in pharmaceutical formulation to produce stable, solution preparations and microcrystalline suspensions used for diabetes treatment. Regular insulin preparations contain zinc ions in sufficient concentrations to promote self-association into hexamers, increasing chemical stability.¹⁰⁹ Phenolic compounds, additionally added as antimicrobial agents, have also been shown to have a profound stabilizing effect on deamidation as well as on intermolecular crosslinking reactions.¹⁰⁹ In addition to stabilizing insulin against undesirable chemical degradation, promotion of the hexamer conformation is also beneficial by preventing physical denaturation. Insulin fibrillation,

or nonnative aggregation, is thought to occur by interactions between partially denatured monomers.¹¹⁰ The addition of excess zinc ions has also been shown to physically stabilize neutral solutions of insulin without affecting the rate of absorption following subcutaneous injection.¹¹¹ Thus solution preparations of insulin are formulated to promote hexamer formation, thereby providing the most stable form of the hormone. The implications of this associated state on insulin pharmacology were not fully appreciated until recently.

A scheme describing the putative events in the subcutis following the subcutaneous injection of a soluble insulin preparation is shown in Fig. 28-8A.^{7,80,112} As previously described, the predominant associated state of insulin in the formulation is the hexamer with zinc ions and phenolic molecules bound. Diffusion in the interstitial space causes dilution of the insulin concentration, resulting in the progressive dissociation of the hexamer into smaller units.¹¹³ Hexamer dissociation is facilitated by diffusion of the liganded phenolic molecules and zinc ions. The phenolic molecules likely diffuse initially in the process to the surrounding tissues, resulting in the conversion of R_6 hexamers to the T_6 type. Whether or not the $R \rightarrow T$ conversion plays any significant role in further delaying the dissociation process is not clearly understood. A 50- to 100-fold dilution is required to produce mainly dimers of insulin, whereas the concentration must be reduced at least 1000-fold to achieve a predominant population of monomers. One main feature of this model is that insulin can only be absorbed effectively in its monomeric or dimeric form. It is not known if the insulin hexamer can cross the capillary membrane or whether its size restricts passage relative to the monomer or dimer forms.

NEW HUMAN INSULIN ANALOGS WITH IMPROVED PHARMACOKINETIC AND PHARMACODYNAMIC PROPERTIES

The need for new insulins with improved pharmacokinetic and pharmacodynamic profiles has been well documented.^{6,14,28,80,114} In particular, regular soluble insulins act too slowly and last too long, whereas the basal depot insulins do not act long enough and are associated with peak effects rather than providing flat, peakless profiles. With the advent of recombinant DNA technology (human insulin was the first pharmaceutical product derived from recombinant DNA technology in the early 1980s⁷⁵) came the ability to prepare virtually any insulin analog desired. Not only did this new technology provide an important medical product, it gave insulin researchers the wherewithal to design, prepare, and test human insulin analogs for desirable pharmacokinetic and pharmacodynamic properties. Guided by the sophisticated x-ray structural data for insulin crystals and the many physicochemical studies on insulin discussed in the preceding sections, insulin researchers have designed insulin molecules with definite targets. The initial target was the design of insulins capable of giving more rapid serum insulin concentrations with a shorter duration of action compared to the regular soluble insulins.⁸⁰ This type of rapid-acting insulin should have the capability of decreasing the magnitude of mealtime glucose excursions while reducing the potential for late hypoglycemia, coupled with improved convenience for the patient with diabetes.¹¹⁵

As previously discussed, there is a delay in absorption of insulin upon subcutaneous injection of regular preparations. The absorption of insulin is influenced by a number of factors, many of

FIGURE 28-8. Schematic representation of the putative events following subcutaneous injection of regular human insulin (A) and a formulated monomeric analog [e.g., Humalog, Lys^{B28}Pro^{B29}] (B). The initial event involves diffusion of phenolic preservative into the surrounding tissue and dissociation of phenolic molecules from the hexamer complexes. Human insulin zinc complexes are relatively stable and require diffusion and dilution for dissociation into smaller absorbable units. A 50- to 100-fold dilution is needed for dissociation to mainly dimers, whereas a further 1000-fold dilution is required to produce predominantly monomeric insulin that can be absorbed. In contrast, both zinc ions and phenolic molecules are required to stabilize the hexameric complex of Lys^{B28}Pro^{B29}. Because of the greatly reduced dimerization constant of the analog, hexamer dissociation occurs at much lower dilutions. Thus free Lys^{B28}Pro^{B29} monomers are produced faster than human insulin, resulting in more rapid absorption. The diagrams are based on models proposed in Ciszak and colleagues,⁴⁶ Bakaysa and associates,¹¹² and Brange and coworkers.⁸⁰ (Figure adapted with permission from Brange et al.⁷)

which also affect the self-association state by facilitating dissociation. For example, dilute insulin concentrations and increased blood flow would be expected to promote faster dissociation of the hexamer. Based on the premise that small molecules diffuse faster and would be unrestricted in passing through the capillary membrane, the absorption process could be accelerated by reducing the self-association state of insulin. This hypothesis forms the basis for designing insulin analogs with reduced propensity towards self-association that would display a more rapid onset of action and shorter duration of action after subcutaneous injection. Two such human insulin analogs were introduced in recent years as very rapid-acting mealtime insulins, namely Lys^{B28}Pro^{B29}-human insulin (insulin lispro; Humalog[®]) and Asp^{B28}-human insulin (insulin aspart; NovoRapid[®]). Although both of these new insulins exist as stable zinc hexamers in their respective formulations, the

rapid action derives from their quicker dissociation from the hexameric state compared to regular human insulin after subcutaneous injection (see Fig. 28-8).

Another goal was the design of insulins that would produce a more physiologic basal insulin profile, preferably soluble, long-acting insulins capable of duplicating the nearly peakless profile of bovine Ultralente insulin shown in Fig. 28-6.⁹⁰ The recently-introduced Gly^{A21}Arg^{B31}Arg^{B32}-human insulin (insulin glargine; Lantus[®]) fits into this category. In this molecule, the two additional positive charges at the C terminus of the B chain increase the isoelectric point from ~5.4 to ~6.7; this allows a soluble formulation at a slightly acidic pH, a formulation that becomes less soluble when injected into the subcutaneous tissue at physiologic pH.¹⁴ These three new insulins are discussed in more detail in the following sections and are illustrated structurally in Fig. 28-9. See also

FIGURE 28-9. Primary structure of human insulin in white circles (21-residue A chain connected to 30-residue B chain via disulfide bonds) showing positions of modification for the three human insulin analogs. Modification of human insulin to give the basal human insulin analog Gly^{A21} Arg^{B31} Arg^{B32}-human insulin (insulin glargine or Lantus) is illustrated by **black circles**, whereby glycine replaces A21 asparagine and two arginine residues are attached to the C terminus of the B chain. Aspartic acid replaces proline at position B28 (**stippled circle**) to give the rapid-acting human insulin analog Asp^{B28}-human insulin (insulin aspart or NovoRapid). The modification that creates the rapid-acting human insulin analog Lys^{B28}Pro^{B29}-human insulin (insulin lispro or Humalog) is shown by the **gray circles**, indicating the changes whereby the native sequence Pro^{B28}Lys^{B29} is transposed to Lys^{B28}Pro^{B29}.

recent reviews on the clinical aspects of new insulin analogs and their potential in the management of diabetes mellitus.^{14,114}

Lys^{B28}Pro^{B29}-Human Insulin (Insulin Lispro [Humalog])

As shown in Figs. 28-1 and 28-9, the native amino acid sequence of human insulin at positions 28 and 29 in the B chain is Pro-Lys. Researchers found that inverting this sequence to Lys-Pro resulted in an insulin analog with a weakened tendency to self-associate into dimers,^{108,116} a characteristic that explains its more rapid onset of action and shorter duration in comparison to regular human insulin.^{115,117-121} The physicochemical basis for this rapid activity has been reviewed recently by DeFelippis and colleagues.²⁸ The Lys^{B28}Pro^{B29} inversion analog has been crystallized in the presence of both zinc ions and phenol at pH 5.9, and its three-dimensional structure as determined by x-ray crystallography to 2.3 Å resolution revealed the T₃R₃[†] hexamer conformation.⁴⁶ The structure is isomorphous with the uncomplexed native human insulin structure; however, localized structural differences in the C-terminal region of the B chain caused by the sequence inversion result in the elimination of two critical hydrophobic interactions involving Pro^{B28} and weakening (lengthening) of two β-pleated sheet hydrogen bonds that stabilize the dimer.

The x-ray crystallographic results demonstrate that despite modifications to the insulin sequence intended to disrupt self-association, hexamer formation can occur as observed in the solid state. The finding that excipients prone to induce hexamer formation in native insulin also do so for monomeric analogs has important implications for pharmaceutical formulation since the entire design premise is based on eliminating self-association. However, for monomeric analogs to be viable as commercial solution preparations, excipients such as antimicrobial agents are required in the

formulation, and zinc ions might also be included to achieve stability.^{109,110} On the other hand, if the addition of such excipients causes comparable self-association of the analog in solution, the potential for delayed dissociation could negatively impact its rapid time action. This situation creates a predicament for the effective formulation of a stable, solution preparation of a monomeric insulin analog, while simultaneously maintaining its desirable pharmacologic attributes. Nevertheless, these practical formulation issues were considered during formulation development of the commercially available monomeric insulin analog Lys^{B28}Pro^{B29}-human insulin (insulin lispro, Humalog) preparation, which contains both zinc ions and m-cresol as excipients. Despite this fact Lys^{B28}Pro^{B29} maintains its rapid time action properties as shown by the data presented in Fig. 28-10.

The x-ray crystallographic studies on crystals of Lys^{B28}Pro^{B29} grown in the presence of zinc ions and phenol revealed a hexamer conformation.⁴⁶ Although the commercial preparation of Lys^{B28}Pro^{B29} (Humalog) is a solution formulation, the structural data obtained in the solid state was used to propose a possible explanation for unaltered time action observed *in vivo*. The authors suggest that the localized structural perturbations of the analog hexamer complex relative to human insulin (see earlier discussion) coupled with the requirement for zinc ions and phenol for stabilization of the hexamer explains why formulated Lys^{B28}Pro^{B29} readily dissociate in subcutaneous tissue. Ciszak and associates⁴⁶ hypothesize that initial diffusion of bound phenolic preservative into surrounding tissue destabilizes the analog hexamer, resulting in dissociation into monomer subunits at millimolar concentrations. This hypothesis is supported by a study of the solution-state properties of Lys^{B28}Pro^{B29} in the presence and absence of zinc ions and phenolic compounds monitored by static light scattering.¹¹² These static light scattering results, monitoring the *in vitro* dissociation of the Lys^{B28}Pro^{B29} complex upon dilution in buffer, showed that the

FIGURE 28-10. Blood glucose excursions (A) of ten T1DM patients after consumption of a meal rich in rapidly-absorbable carbohydrates [pizza, sugar-sweetened cola, and tiramisu (total caloric content was 1016 kcal)]. After a subcutaneous injection of 15.4 ± 3.5 U at time zero, the meal was eaten within 20 minutes. On one of two study days, insulin lispro (open circles) was injected; on the other day regular human insulin (solid circles) was injected. Blood glucose was kept constant at 6.7 mmol/L^{-1} in the 3 hours prior to the meal by means of a glucose clamp. Free plasma insulin concentrations (B) of ten T1DM patients induced by an intravenous insulin infusion of $0.2 \text{ mU} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$ (maintained throughout the study) and subcutaneous injection immediately prior to the meal at time zero. Injections of insulin lispro (open circles) or regular human insulin (solid circles) were administered as in A. (Reproduced with permission from Heinemann et al.¹²²)

analog becomes less associated as protein concentration is reduced, whereas human insulin formulated under similar conditions was essentially hexameric regardless of the dilution. Thus these results illustrate the weaker hexamer association of the analog. See Fig. 28-8 for a schematic representation of the putative events following subcutaneous injection of regular human insulin compared to a formulated monomeric insulin analog such as Humalog.

The pharmacokinetics and glucodynamics of insulin lispro have been studied extensively as reviewed recently by Heinemann and Woodworth.¹²¹ The studies showed that subcutaneous administration of clinically relevant doses of insulin lispro gave a more rapid absorption and elimination profile than regular human insulin. After intravenous administration, insulin lispro and regular human insulin gave nearly identical clearance and volumes of distribution, and produced identical metabolic responses, indicating a 1:1 potency ratio.¹²¹ Differences in absorption between insulin lispro and regular human insulin, but equivalence in distribution

and clearance, were observed in healthy volunteers and in patients with type 1 or type 2 diabetes.¹²¹ The authors concluded that the more rapid absorption of insulin lispro allows a better mealtime insulin substitution than regular human insulin.¹²¹ This conclusion was validated by a randomized, double-blind, glucose clamp-controlled study, the results of which are shown in Fig. 28-10. In this study, 10 patients with well-controlled T1DM received subcutaneous injections of either insulin lispro or regular human insulin (15.4 ± 3.5 U; the exact dose selected by the patients based on their own experience), followed immediately by ingestion of a meal rich in rapidly-absorbable carbohydrates.¹²² Maximum blood glucose excursions were significantly lower and returned to baseline earlier with insulin lispro than with regular human insulin. The free plasma levels of the analog increased more rapidly and decreased faster than human insulin.

Many of the clinical studies on insulin lispro have been summarized by Anderson and Koivisto¹¹⁵ and by Bolli and colleagues.¹⁴ Insulin lispro's rapid absorption rate and short duration of action provide several advantages for patients on insulin lispro therapy as compared to regular human insulin. Insulin lispro was developed particularly for mealtime therapy through injection immediately before the meal and when appropriately used in this manner consistently reduces the postprandial rise in blood glucose as compared to regular human insulin in patients with type 1 or type 2 diabetes.¹¹⁵

If insulin lispro is administered shortly after a meal, the postprandial rise in blood glucose is no greater than if regular insulin is injected immediately or shortly before a meal as shown by Schemthaner and associates.¹²³ These clinical investigators studied 18 patients with type 1 diabetes who injected regular human insulin at 40, 20, or 0 minutes before the start of a standardized meal or insulin lispro at 20 or 0 minutes before or 15 minutes after the start of the meal. In this study, the optimal time for bolus injection was immediately before the meal for insulin lispro and 20 minutes before the meal for regular human insulin, based on blood glucose excursions. Insulin lispro injected 15 minutes after the start of the meal was comparable to regular human insulin injected from 40 to 0 minutes before the meal. In their review, Anderson and Koivisto reported that a meta-analysis of over 12,000 patients with T1DM demonstrated a 30% reduction in severe hypoglycemia during insulin lispro therapy.¹¹⁵ Additionally, insulin lispro appears to be no more immunogenic than regular human insulin as determined in four 1-year international trials including 317 patients with T1DM and 291 patients with T2DM previously treated with regular human insulin.¹²⁴ Coupled with a basal insulin therapy adjusted to cover premeal and nocturnal periods, insulin lispro may provide a more physiologic insulin therapy, as emphasized by Bolli and colleagues.¹⁴ Also, insulin lispro administered by a continuous subcutaneous insulin infusion (CSII) regimen is a viable alternative to a multiple daily insulin injection regimen for patients on intensive insulin therapy.¹²⁵

The introduction of $\text{Lys}^{\text{B28}}\text{Pro}^{\text{B29}}$ to the commercial market has created interest in exploring other formulations of this analog. Cocrystallization of the analog with protamine produced a suspension called neutral protamine lispro (NPL) with similar physicochemical properties to NPH insulin.¹⁰⁶ The motivation for making this suspension was to allow the preparation of stable mixtures with soluble $\text{Lys}^{\text{B28}}\text{Pro}^{\text{B29}}$. Such preparations could be useful for basal/bolus therapy in type 1 patients. Pharmacologic evaluation of NPL in dogs has shown that the preparation has an intermediate time action.¹⁰⁶ A clinical trial conducted in type 1 diabetic subjects determined that NPL was equally effective as human insulin NPH

in controlling overnight glycemia.¹²⁶ In a euglycemic glucose clamp study conducted in normal subjects, three mixtures of soluble Lys^{B28}Pro^{B29} combined with NPL in ratios of 75:25, 50:50, and 25:75 were evaluated.¹²⁷ The results of this study confirmed that the pharmacokinetic and pharmacodynamic properties of Lys^{B28}Pro^{B29} were maintained in the mixtures. Data from other clinical trials conducted in type 2 patients have reported that the 25:75 analog mixture provides improved postprandial glycemic control relative to a human insulin mixture containing 30% regular insulin and 70% NPH insulin.^{128,129}

Asp^{B28}–Human Insulin (Insulin Aspart [NovoRapid])

Asp^{B28}–human insulin (herein referred to as Asp^{B28} and insulin aspart) was first described in 1988 by Brange and colleagues.¹⁰⁷ As with Lys^{B28}Pro^{B29} insulin, Asp^{B28} was designed as a rapid-acting mealtime insulin with a lesser propensity to self-associate compared to regular insulin. Asp^{B28} refers to an analog prepared by substituting aspartic acid for proline at position 28 in the B chain of human insulin as illustrated in Fig. 28-9. Brange and associates reported on various approaches for producing monomeric insulins.^{80,107} In the case of Asp^{B28}, the primary hypothesis was to selectively introduce an amino acid with a negatively-charged side-chain carboxyl group to create charge repulsion and weaken the monomer-monomer interaction. Although charge repulsion may play some role in hindering self-association, a more likely explanation for the more rapid action of this human insulin analog concerns the removal of proline from position B28, which eliminates a key hydrophobic interaction between monomers.⁷ The Asp^{B28} analog has recently been crystallized in the presence of zinc and phenol or m-cresol;¹³⁰ the analog crystallized as R₆ hexamers with a number of phenolic molecules (m-cresol or phenol) bound at specific sites. This contrasts to Lys^{B28}Pro^{B29} insulin crystal studies, which showed a T₃R₃[†] hexamer conformation. The replacement of proline with aspartic acid at position B28 causes increased conformational flexibility in the C terminus of the B chain, resulting in loss of critical intermolecular van der Waals contacts between positions B28 and GlyB23' at the monomer-monomer interface, explaining the monomeric nature of the analog.¹³⁰ As mentioned previously, this explanation is contrary to the original design hypothesis of introducing charge repulsion in the interface.^{80,107} However, it has been speculated that charge repulsion may contribute to hexamer destabilization, causing rapid dissociation to monomers.⁷

The pharmacokinetics and pharmacodynamics of Asp^{B28} have been investigated in normal subjects,^{131–139} and, as reviewed by Lindholm and Jacobsen,¹⁴⁰ subcutaneously-administered Asp^{B28} showed an absorption profile with a time to reach peak concentration about half that of human insulin, a peak plasma drug concentration approximately twice as high, and a shorter residence time (Fig. 28-11). These observations are similar to those obtained in the insulin lispro studies and are consistent with the notion that more rapid action can be achieved using insulin analogs with impaired self-association characteristics. Similarly, clinical trials in patients with type 1 or type 2 diabetes have demonstrated that insulin aspart, like insulin lispro, is efficacious as a very rapid-acting mealtime insulin, resulting in improved postprandial glucose excursions when compared to the traditional regimen of regular human insulin given approximately 30 minutes before the meal.^{140–149} Both insulin aspart and insulin lispro, in conjunction with appropriate basal insulin therapy, appear to more closely mimic the endogenous insulin profile in blood compared with

FIGURE 28-11. Glucose infusion rates (A) and serum insulin concentrations (B) after subcutaneous injection of 0.15 U/kg⁻¹ body weight Asp^{B28} (—) or regular human insulin (····) into the abdominal region 14 normal subjects. Baseline insulin concentrations were established by intravenous insulin infusion of 0.15 mU·kg⁻¹ min⁻¹. (Reproduced with permission from Heinemann et al.¹³³)

human insulin.^{140,150} Insulin aspart is also an alternative for intensive insulin therapy by CSII,¹⁵¹ and the analog can be formulated with protamine in a 30:70 mixture.^{152–153} Although insulin aspart and insulin lispro are generally assumed to be quite similar in their respective pharmacokinetic and pharmacodynamic properties, there is a paucity of data showing direct comparisons. Hedman and associates¹⁵⁴ designed such a comparison, in which 14 patients with T1DM were administered 10 U of each analog on alternate days immediately before consuming a standardized breakfast in a single blind randomized crossover study. As expected, both insulins were absorbed much faster than human insulin after subcutaneous injection, with higher insulin peaks and shorter duration of action (based on historic data). The main finding in this direct comparison of insulin aspart and insulin lispro is that the free plasma insulin levels resemble each other, with insulin lispro showing a slightly more rapid uptake, reaching the maximum peak concentration earlier, followed by a more rapid decline.

Gly^{A21}Arg^{B31}Arg^{B32}–Human Insulin (Insulin Glargine [Lantus]) (also 21^A-Gly-30^Ba-L-Arg-30^Bb-L-Arg-Human Insulin)

This human insulin analog (formerly known as HOE 901) was designed as a soluble, basal insulin. The design concept involved introducing two arginines into the primary structure of human insulin

(see Fig. 28-9), thereby shifting the isoelectric point from about 5.5 to a more neutral pH, a maneuver that greatly reduces the solubility of the insulin analog upon injection into the neutral milieu of the subcutaneous tissue. An insulin-like molecule with this characteristic occurs naturally in that diarginyl insulin (insulin-Arg^{B31}Arg^{B32}) is one of the intermediate products formed during the proteolytic conversion of proinsulin to insulin in the pancreatic β cell.¹⁵⁵ The same diarginyl insulin is also formed under some manufacturing conditions for recombinant human insulin.⁷⁶ The replacement of asparagine with glycine at position 21 in the A chain is necessary to ensure acceptable chemical stability for the slightly acidic, soluble glargine formulation. This is a crucial modification as acidic insulin solutions are known to degrade by mechanisms that involve the COOH-terminal asparagine at position A21.¹⁵⁶

X-ray crystallographic analysis of Gly^{A21}Arg^{B31}Arg^{B32}-human insulin indicates that the hexamer structure is more stable than the native hormone and that the analog crystallizes as R₆ hexamers in the presence of phenol.¹⁵⁷ Crystal stability is mainly attributed to interactions between neighboring hexamers, and a seventh molecule of phenol was also detected in the structure, located in a surface depression of trimer I.¹⁵⁷ The phenolic hydroxyl group donates a hydrogen bond to the side chain of a glutamic acid residue of a neighboring hexamer in the crystal lattice. This interaction was proposed to increase the attractive interhexamer forces contributing to the stabilization of the analog crystals formed after subcutaneous injection.¹⁵⁷

The clinical efficacy and safety of insulin glargine have been reported recently in studies with healthy volunteers,¹⁵⁸⁻¹⁵⁹ in patients with T1DM,¹⁶⁰⁻¹⁶⁶ and in patients with T2DM.¹⁶⁷⁻¹⁶⁸ Comparisons were generally made using once-a-day injection for glargine versus once- or twice-a-day injections for NPH. The general consensus is that this new soluble, long-acting insulin provides more stable blood glucose control with a nearly peakless pharmacodynamic profile, in contrast to the peaks seen with NPH insulin (see Fig. 28-12). Also, there appears to be a safety benefit in terms of less nocturnal hypoglycemia. Lepore and coworkers¹⁶⁶ compared insulin glargine against NPH insulin, Ultralente human insulin, and against a CSII regimen. The authors concluded that

glargine is a peakless insulin, that it lasts nearly 24 hours, that it shows lower intersubject variability than NPH and Ultralente, and that it closely mimics CSII. Thus insulin glargine represents a new soluble basal insulin that may be an important part of the basal-bolus equation along with the new mealtime insulins (insulin lispro and insulin aspart).¹⁶⁹ However, because of formulation incompatibility, the acidic insulin glargine formulation should not be mixed with either insulin lispro or insulin aspart formulations.

CONCLUSIONS AND FUTURE OUTLOOK

Physiological insulin secretion in normal individuals is characterized by stimulated and basal phases. The goal of effective diabetes treatment is to simulate this profile with appropriate injections of insulin. While there have been improvements in the area of pharmaceutical formulation, the time-action profiles of the various commercially available insulin preparations do not adequately approximate endogenous secretion. Clinical data indicating that effective blood glucose control reduces the progression of complications associated with diabetes has further driven efforts to optimize subcutaneous injection therapy. Since little more could be done in terms of improving formulation, recent attention has focused on manipulating the properties of the insulin molecule itself. Recombinant DNA technology and continued advancement in insulin structural determinations have provided the tools to explore this new area of research.

Clinical studies have demonstrated that the absorption of subcutaneously injected insulin is influenced by a variety of factors, none of which can be sufficiently controlled by the patient to achieve more physiologic time-action profiles. Until recently, the relationship between the structural properties of insulin and the absorption process were not fully appreciated. The excipients included in soluble regular insulin preparations to impart stability and satisfy other regulatory requirements promote hexamer assembly. Based on the hypothesis that diffusion and dilution of the insulin hexamer at the injection depot may influence pharmacokinetics and pharmacodynamics, insulin analogs with reduced propensity towards self-association were designed and tested. The physicochemical properties of a number of these analogs confirmed that self-association can be manipulated by selected amino acid modification of the native sequence, and so called "monomeric" insulins could indeed be synthesized. Subsequent *in vivo* testing has demonstrated that the pharmacokinetic and pharmacodynamic properties of these analogs following subcutaneous administration better simulate meal-stimulated secretion compared to human insulin. Two of these analogs (insulin lispro and insulin aspart) have received regulatory approval and are commercially available under the trade names of Humalog and NovoRapid, or Novolog, respectively. Interestingly, a prerequisite for the commercial viability of Lys^{B28}Pro^{B29} was a suitable formulation with the inclusion of excipients found to induce self-association. These formulation conditions appear to undermine the original concept of eliminating hexamer association. However, Lys^{B28}Pro^{B29} hexamers were determined to be destabilized relative to human insulin such that the analog's desirable pharmacokinetic and pharmacodynamic properties are not impacted by formulation. The same is true for insulin aspart.

The strategy of producing monomeric analogs to improve prandial insulin requirements has been very successful. However, basal insulin needs must also be satisfied for effective therapy. NPH and Ultralente suspensions currently used for basal therapy

FIGURE 28-12. Time-action profile of insulin glargine (Lantus) and NPH human insulin, showing the glucose infusion required to maintain plasma glucose concentration at the target of about 130 mg/dL (7.2 mmol/L) in 20 patients with T1DM after injection of either 0.3 U/kg insulin glargine or NPH insulin. The NPH study was terminated at 20 hours because of excessive hyperglycemia. (Modified with permission from commentary by Bolli et al.¹⁶⁴)

were developed long before physiologic insulin secretion was understood. Pharmacologic studies of these suspensions have demonstrated that the pharmacokinetic and pharmacodynamic properties do not simulate the prolonged, low-level release profile of endogenous insulin secretion. Since these suspensions also require agitation to homogeneously disperse the solid particles prior to injection, they are somewhat more complicated for patients to use. Therefore, the newly-approved, soluble, long-acting insulin preparation insulin glargine (Lantus) is an additional product for patients and diabetes caregivers in the continual quest to obtain the best blood glucose control possible.^{169,170} Additional insulin candidates are still in the research stage. One in particular is in clinical development. Insulin detemir [Lys^{B29}(N-tetradecanoyl) des(B30) human insulin] is a soluble insulin derivative being developed as a soluble, basal insulin. Like native insulins, it exists in the formulation primarily in the hexameric state.¹⁷¹ The fatty acid side chain apparently assists in hexamer aggregation as well as to delay hexamer dissociation and absorption.¹⁷² Also, the fatty acid side chain of the monomeric insulin derivative binds to albumin and subsequently slowly dissociates from the albumin, prolonging time action.¹⁷³ While results from an earlier study in normal volunteers gave inconclusive results on the potential use of insulin detemir as a basal insulin,¹⁷⁴ results of clinical studies in patients with T1DM suggest insulin detemir was as effective as NPH in maintaining glycemic control, but only when administered at a higher molar dose.¹⁷¹

There appears to be little that can be done to further improve upon the pharmacologic properties of the monomeric analogs for subcutaneous injection therapy. The properties of these analogs are now being exploited in other formulations. For example, in an effort to optimize basal-bolus therapy, intermediate-acting protamine suspensions of insulin lispro and insulin aspart have been developed for use in premixed preparations. The rapid time-action profile of the soluble fraction of the analog is maintained in these preparations. In terms of the promising basal analog formulation, Lantus, the prolongation mechanism involves an *in situ* precipitation at the injection depot rather than injection of a preformed NPH or Ultralente suspension. What potential improvements can be devised to improve upon this approach, or whether a totally different insulin analog concept for improving basal therapy can be created remain to be seen.

Intensive Management of Type 1 Diabetes Mellitus

Suzanne M. Strowig

Philip Raskin

INTRODUCTION

The results of the Diabetes Control and Complications Trial (DCCT) resolved any ambiguity regarding the relationship between glycemic control and diabetic microvascular and neuropathic complications.¹ The DCCT showed that an intensive diabetes treatment program that resulted in near-normal glycosylated hemoglobin levels significantly delayed the development and progression of the microvascular complications of diabetes by about 50%. The lowering of the glycosylated hemoglobin level was associated with a curvilinear decrease in the progression of retinopathy (i.e., the lower the level of glycosylated hemoglobin, the less the risk of the development and progression of diabetic complications^{2,3}). Based on these data, the DCCT Research Group recommended that intensive diabetes treatment be instituted in most individuals with type 1 diabetes mellitus (T1DM) with the goal of achieving glycemic levels as close to those of nondiabetic individuals as possible.

The value of intensive diabetes treatment was underscored by the recent publication of the findings in DCCT subjects 4 years after the trial ended.⁴ At the conclusion of the DCCT, subjects who had received conventional therapy were advised to initiate an intensive insulin treatment program. All subjects received subsequent care from their own physicians, and most were enrolled in the Epidemiology of Diabetes Interventions and Complications (EDIC) trial, a long-term observational study.⁵ Although the glycosylated hemoglobin levels were significantly different between the intensively and conventionally treated subjects at the end of the DCCT (7.2% versus 9.1%, respectively), the HbA_{1c} levels in both groups converged during the 4 years following the trial (intensive treatment group, 7.9%; conventional treatment group, 8.2%). Despite this, the subjects who received intensive therapy during the DCCT continued to have a lower risk of retinopathy and nephropathy at the end of year 4 of EDIC compared with those who received conventional therapy during the DCCT. This suggests that the beneficial effect of maintaining near-normal glycemic control persists long after the end of such therapy. Since the DCCT had previously shown that intensive therapy was most effective in preventing complications when introduced during the first 5 years of diabetes, it seems that intensive therapy should be implemented as early as is safely possible, and that such therapy be maintained for as long as possible.

INSULIN REGIMENS

The majority of this chapter describes intensive diabetes treatment techniques. However, since some individuals with T1DM may be candidates for intensive diabetes treatment or may not be willing to accept the personal commitment inherent in such treatment, other insulin regimens, along with their indications, advantages and disadvantages, are discussed. In general, insulin injection regimens consist of a combination of basal insulin (intermediate-acting insulin such as NPH or Lente™, or long-acting insulin such as Ultralente™) and short-acting (regular) or rapid-acting insulin (insulin lispro or insulin aspart). Short- or rapid-acting insulin is given before meals to control postprandial blood glucose levels.

Short- and Rapid-Acting Insulin

The optimal time to inject regular insulin to achieve ideal postprandial blood glucose levels is 30–60 minutes before meals. The peak effect of regular insulin is usually achieved 2–6 hours after injection, and its effects may last from 6 hours to as long as 16 hours. However, since the peak glycemic response to a mixed meal has been found to be between 26 and 70 minutes after ingestion, regular insulin may peak too late to control postprandial blood glucose levels.⁷ There is also the potential for hypoglycemia to occur several hours after the meal.

The rapid-acting insulin analogues insulin lispro and insulin aspart were developed by modifying the amino acid sequence composition of the B chain of the insulin molecule. These alterations reduce the stability of the insulin monomer-monomer interactions, leading to a more rapid dissociation and subcutaneous absorption of the insulin.⁸ With insulin lispro, lysine and proline at positions 28 and 29 of the B chain of the human insulin molecule have been reversed. In insulin aspart, the proline at position B28 has been replaced by aspartic acid. The pharmacokinetic effects of the modifications in the insulin molecule are: (1) The insulin is absorbed and eliminated faster than regular insulin, producing a shorter duration of action (3 hours versus 6 hours), and (2) the serum concentration peaks more than two times higher and in less than half the time (42 minutes versus 101 minutes) of regular insulin (Fig. 29-1).^{9–12} Studies have shown that postprandial blood glucose levels are improved with the use of these insulin analogues,^{13–18} although preprandial and fasting blood glucose levels

FIGURE 29-1. Effects of subcutaneous administration of insulin lispro and regular insulin on serum insulin concentrations. (Reproduced with permission from Holleman et al.⁹)

may be elevated because of the short duration of action. A reduction in the frequency of hypoglycemia^{13,19–21} and an improvement in patient satisfaction^{19,22} have been reported with the use of rapid-acting insulin.

There are several clinical considerations associated with the use of rapid-acting insulin. Since the onset of action is fairly rapid, insulin lispro and insulin aspart can be taken within 15 minutes before the meal.²³ Because of its short duration of action, more basal insulin is usually required to control preprandial and fasting blood glucose levels.^{24,25} A morning and evening injection of intermediate- or long-acting insulin is usually necessary. Patients may not require between-meal snacks, and in fact may need additional injections of rapid-acting insulin if snacks are desired.²⁶

Some practitioners compensate for the shorter duration of action associated with rapid-acting insulin by combining it with regular insulin before meals. At present, there is no evidence to suggest that this combination of insulin provides improved blood glucose control.²⁷

Twice-Daily Insulin Injections

Single daily doses of insulin rarely result in 24-hour glycemic control, and are not recommended. A twice-daily insulin injection regimen is usually given as a combination of short- (regular) or rapid-acting (lispro or aspart) insulin and intermediate-acting (NPH or Lente) insulin before breakfast and supper. This regimen provides insulin availability for each meal plus sustained insulin action overnight (Fig. 29-2). The total daily dose of insulin is often determined by body weight, usually between 0.5 and 1.0 U/kg per day.²⁸ Generally, two-thirds of the total daily dose is given in the morning before breakfast, and one-third is given in the evening before supper, with each injection consisting of two-thirds intermediate-acting insulin and one-third short- or rapid-acting insulin. An insulin algorithm can be employed to adjust the regular insulin or rapid-acting insulin analogues based on prebreakfast and presupper blood glucose levels.

Insulin with a premixed ratio of intermediate- (i.e., NPH) and short- or rapid-acting insulin is available for patients who have physical and cognitive limitations. A patient can draw up a single

FIGURE 29-2. Representation of idealized periods of insulin effect for a split-and-mixed insulin regimen, consisting of two daily doses of short-acting (regular) and intermediate-acting insulin. Symbols: **B**, breakfast; **L**, lunch; **S**, supper; **HS**, bedtime; **arrows**, time of insulin injection 30 minutes before meal; **Reg**, regular or short-acting insulin effect; **NPH/LENTE**, intermediate-acting insulin effect. (Reproduced with permission from Hirsch et al.²⁸)

dose of insulin from one vial of 70/30 insulin that consists of 70% NPH and 30% regular insulin, or of 75/25 insulin that consists of 75% NPL (neutral protamine lispro) and 25% insulin lispro. Although these mixtures are easy to use, they decrease the flexibility of dose adjustments. For example, 30 units of 70/30 insulin taken before breakfast may contain a sufficient amount of intermediate-acting insulin (21 units) to control presupper blood glucose concentrations, but may provide too much short-acting insulin (9 units) to control prelunch blood glucose levels, resulting in hypoglycemia before lunch. Lowering the dose of 70/30 insulin would correct the hypoglycemia before lunch, but would result in hyperglycemia before supper. In this situation, the patient, if capable, would need to individually draw up the intermediate- and short- or rapid-acting insulin and mix in one syringe.

Adjustments in the short- or rapid-acting insulin component of the prebreakfast dose are made based on the subsequent examination of postbreakfast and prelunch blood glucose concentrations. Changes in the intermediate-acting insulin component of the prebreakfast dose are based on the examination of presupper blood glucose concentrations. Similarly, the subsequent examinations of postsupper and bedtime blood glucose levels determine changes in the short- or rapid-acting insulin component of the presupper insulin dose, whereas the fasting and 3 AM blood glucose levels are used to make changes in the intermediate-acting component of the presupper insulin dose. Insulin dosages should be changed by 10–20% whenever an adjustment is indicated. Once done, it is best to wait several days before making further changes.

Although twice-daily mixed insulin provides adequate insulin availability throughout the day, there are several pitfalls to this regimen. Hypoglycemia late in the afternoon and in the middle of the night related to intermediate acting insulin frequently occurs, especially with the new formulations of biosynthetic human insulin, which have a shorter duration of action than the animal insulins used in the past. Prebreakfast hyperglycemia can also occur because insulin action wanes. Attempts to decrease morning hyperglycemia by increasing the presupper dose of intermediate-acting

insulin may only aggravate the frequency and severity of nocturnal hypoglycemia. Correcting prebreakfast hyperglycemia can be resolved by taking the evening dose of intermediate-acting insulin at bedtime. Of course, the patient must now take three insulin injections daily (Fig. 29-3).

A twice-daily insulin injection plan is the least flexible regimen. Insulin must be taken at approximately the same time every day (± 1 hour). Failure to do this creates periods of insulin deficiency and periods of overinsulinization when insulin action overlaps. Meal times must also be consistent since food must be eaten when insulin action peaks. Problems in blood glucose control may result when the patient sleeps late, travels, changes work hours, or eats out. When diabetic patients have a lifestyle that demands flexibility, this regimen is often difficult to manage, and a more intensive regimen involving three or more injections per day or an insulin pump has distinct advantages.

Multiple Daily Insulin Injections

Multiple daily injection (MDI) regimens can be done in a variety of ways. Three injections per day using a mixture of intermediate- and short- or rapid-acting insulin before breakfast, short- or rapid-acting insulin before supper, and intermediate-acting insulin at bedtime can be effective for diabetic patients who experience frequent nocturnal hypoglycemia and prebreakfast hyperglycemia using only two injections per day (Fig. 29-3). This regimen also provides additional control and flexibility for those who do not wish to use the more intensive injection schedules. It may be most suited to individuals who desire better glycemic control and/or flexibility but do not wish to take or frequently forget the prelunch injection. This is often the case in children and adolescents who may find it difficult to take a prelunch injection while at school.

Four daily insulin injections using short- or rapid-acting insulin before each meal and intermediate- or long-acting insulin once or twice a day allows patients more flexibility. A regimen of four daily injections using intermediate-acting insulin at bedtime (Fig. 29-4) avoids problems associated with peak afternoon insulin activity from an injection of intermediate-acting insulin taken before breakfast. Short-acting insulin can be adjusted to adequately

FIGURE 29-3. Representation of idealized periods of insulin effect for a three-injection-a-day regimen in which split-and-mixed dose is given in the morning, short-acting (regular) insulin before supper, and intermediate-acting insulin is delayed until bedtime. Symbols: **B**, breakfast; **L**, lunch; **S**, supper; **HS**, bedtime; **arrows**, time of insulin injection 30 minutes before meal; **Reg**, regular or short-acting insulin effect; **NPH/LENTE**, intermediate-acting insulin effect. cover each meal, thus controlling postprandial hyperglycemia and facilitating better overall glycemic control throughout the day. However, if rapid-acting insulin (insulin lispro or insulin aspart) is used before meals instead of short-acting insulin, a morning injection of intermediate-acting insulin in addition to the bedtime injection of intermediate-acting insulin will likely be needed. More basal insulin is required when rapid-acting insulin is used because of the short duration of action.^{24,25}

Ultralente insulin can be used in MDI regimens in place of intermediate-acting insulin to meet basal insulin needs (Fig. 29-5). Ultralente insulin can be given as one injection in the morning, but is usually divided so that half the dose is taken before breakfast and the other half before supper (preferable when rapid-acting insulin is given before meals). Short- or rapid-acting insulin is given before each meal to provide meal-related insulinemia. Ultralente insulin is considered a sustained, long-acting "peakless" insulin that can provide effective basal insulinemia. There is evidence to

FIGURE 29-5. Representation of idealized periods of insulin effect for a multiple dosage regimen using premeal short-acting (regular) insulin and basal insulin as Ultralente. Symbols: **B**, breakfast; **L**, lunch; **S**, supper; **HS**, bedtime; **arrows**, time of insulin injection 30 minutes before meal; **Reg**, regular or short-acting insulin effect. (Reproduced with permission from Hirsch et al.²⁸)

suggest, however, that small peaks in its action occur 15–24 hours after injection, particularly with newer human preparations.^{29,30} Since small peaks in the activity of Ultralente insulin are difficult to predict, regimens using Ultralente insulin may be less preferable to those using intermediate-acting insulin.

Insulin analogues that provide more effective basal insulin delivery may make MDI regimens even more successful at achieving glycemic goals. Insulin glargine, recently approved by the FDA, results from two modifications of human insulin. Two arginine molecules which are positively charged are added at the C terminus of the B chain. The asparagine molecule at position 21 in the A chain is replaced by glycine. This leads to a shift of the isoelectric point that results in precipitation at the neutral pH of subcutaneous tissue and thus delayed absorption.³¹ Insulin glargine is peakless, lasts nearly 24 hours, and has lower intersubject variability than NPH and Ultralente insulin.^{30,32} Studies have shown that insulin glargine given once daily results in lower fasting blood glucose levels and a comparable or lower incidence of hypoglycemia compared with intermediate-acting insulin given one or more times daily.^{33,34} Insulin glargine is a clear solution at a pH of 4.0 and cannot be diluted or mixed in a syringe with any other insulin. Patients who are switching from once-daily doses of NPH or Ultralente insulin to a once-daily bedtime dose of insulin glargine should start on the same dose of insulin glargine as was previously used while on intermediate or Ultralente insulin. Patients being switched from twice-daily doses of NPH or Ultralente insulin to a once-daily bedtime dose of insulin glargine should have their insulin glargine dose reduced by 20% from the previous total daily dose of NPH or Ultralente insulin.

Other insulin analogues for basal insulin delivery are under development. One such analogue is insulin detemir, which is created by acylation of LysB29 with a saturated fatty acid, and by removing the amino acid residue at position B30. This analogue has a high affinity for albumin, which results in a delay in the absorption of insulin and a prolonged duration of action.

When four-injection regimens are used, insulin adjustments are made based on blood glucose levels obtained before and after meals, before bed, and periodically at 3 AM. Changes in the bedtime intermediate or long-acting (Glargine)* insulin are based on 3 AM and fasting blood glucose levels. The morning intermediate-acting insulin is adjusted based on the mid- to late-afternoon and presupper blood glucose reading. The premeal short- or rapid-acting insulin doses are adjusted based on the postprandial and premeal blood glucose levels that follow that injection (i.e., the pre-lunch insulin dose is adjusted based on the blood glucose level after lunch and before supper).

Despite the increased flexibility that multiple insulin injection regimens offer, injections of short-acting insulin should be given within 4–6 hours of one another. Skipping meals and/or injections of short-acting insulin usually results in loss of blood glucose control, although this may be less of a problem with new long-acting insulin analogues. Maintaining this degree of consistency may be a limiting factor for some individuals. In addition, some patients may object to frequent needle injections or having to carry syringes and bottles of insulin with them. Pen-like devices are available (self-contained pens of insulin with a needle attached) that enable a patient to simply dial the desired dose and inject the insulin with relative ease. These devices are simple to use and handy to carry, and may help patients more successfully implement a multiple daily insulin injection regimen.

Inhaled insulin, currently under investigation, may be an option in the future to facilitate implementation of multiple daily

doses of insulin. Aerosolized dry powder insulin is inhaled via a device that enhances inhalation and absorption of the insulin through the alveoli of the lungs. The inhaled insulin is a short-acting insulin that can be administered before meals; intermediate- or long-acting insulin must be given via subcutaneous needle injection one or two times daily in addition to the inhaled insulin. Onset of action and maximal action of inhaled insulin appear to occur sooner than subcutaneously administered regular insulin.³⁵ Preliminary reports suggest that inhaled insulin results in at least comparable levels of glycemic control as subcutaneous insulin.³⁶ The effect of inhaled insulin on pulmonary function continues to be investigated.

Method for Determining Initial Insulin Dosages for MDI Regimens

The total amount of intermediate-(NPH/Lente) or long-acting (Glargine) insulin at bedtime should be 35–50% of the patient's total daily dose. The total dose of NPH/Lente or ultralente insulin can be divided so that 30–40% is given before breakfast, and the remainder is given at bedtime. This is recommended if rapid-acting insulin instead of short-acting insulin is given before meals. The amount of short-acting insulin before each meal can be calculated as a percentage of the total daily dose as follows: breakfast, 20–25%; lunch, 10–15%; dinner, 15–20%; and bedtime, 3–5%.

For example, an insulin regimen consisting of NPH 20 units and regular 10 units before breakfast and NPH 10 units and regular 5 units before dinner could be converted to a four-injection-per-day regimen as follows:

Bedtime NPH insulin:	40% of 45 units ($.40 \times 45$) = 18 units
Regular insulin:	Breakfast, 9 units ($45 \times .20$)
	Lunch, 7 units ($45 \times .15$)
	Dinner, 9 units ($45 \times .20$)
	Bedtime snack, 2 units ($45 \times .05$)

Premeal dosages of short- or rapid-acting insulin can also be calculated based on the patient's dietary intake using the guidelines described below for insulin pump therapy (i.e., 1–2 units per 10–15 grams of carbohydrate). When a patient switches from short-acting insulin (regular) to rapid-acting insulin (lispro), the dose of rapid-acting insulin may need to be reduced, and the dose of basal insulin (intermediate- or long-acting insulin) may need to be increased.

Continuous Subcutaneous Insulin Infusion

Continuous subcutaneous insulin infusion (CSII) is an alternative to MDI when the patient desires improved blood glucose control or greater flexibility in his or her regimen. Of all options, the insulin infusion device permits the greatest degree of lifestyle flexibility and can therefore facilitate achieving glycemic goals. The reasons for this are (1) the insulin pump uses only short- or rapid-acting insulin, making insulin absorption from subcutaneous tissues more predictable, and (2) insulin delivery is similar to that found in nondiabetic individuals since there is continuous basal insulin delivery supplemented by preprandial increases in plasma insulin levels (Fig. 29-6, Table 29-1).³⁷

The pump contains a syringe or reservoir of insulin that connects to a catheter with a 27-gauge needle or teflon cannula at the end. The needle is inserted by the patient into subcutaneous tissue, usually in the abdomen. The user programs the insulin pump to deliver insulin in a basal mode, which is a continuous infusion of insulin usually ranging from 0.5–2.0 U/h. The basal rate is deliv-

FIGURE 29-6. Representation of insulin effect provided by continuous subcutaneous insulin infusion. A continuous infusion (basal rate) is delivered, with premeal boluses administered before meals. Only short- or rapid-acting insulin is used. Symbols: B, breakfast; L, lunch; S, supper; HS, bedtime. (Reproduced with permission from Hirsch et al.²⁸)

ered automatically once programmed. Modern pumps provide the option of automatically delivering multiple different basal rates in a 24-hour period. The majority of patients require one to three basal rates per day, the alternate basal rates being adjusted for lower insulin needs at night or higher insulin needs in the predawn hours. The user programs each premeal bolus before eating.

Although CSII has many advantages, there are several potential problems unique to insulin pump therapy. Interruption of insulin delivery can result in hyperglycemia or ketoacidosis in a matter of hours since there is no depot insulin. Pump malfunction, a dead battery, leakage from the catheter or catheter connections, an empty insulin reservoir, needle displacement, and insulin aggregation in the catheter or in the needle inserted into the abdomen can result in cessation of insulin delivery. Patients must be taught to manage all of the technical components of CSII and be aware of how to deal with problems when they occur. With proper education and follow-up these problems can be avoided. Insulin pumps have alarm systems that warn of pump malfunction, a dead battery, an empty syringe, high pressure, and programming errors.

Another potential problem with CSII is infusion site infections where the needle is inserted. This can be avoided by maintaining good infusion site care and changing the needle every 1–2 days. Infusion site infections are usually resolved with oral antibiotics. Severe infections may have to be surgically incised and drained.

TABLE 29-1. Example of Variable Insulin Dosage Schedule for Insulin Infusion Pump Therapy (Short- or Rapid-Acting Insulin Only)

Blood Glucose (mg/dL)	Units of Insulin			
	Breakfast	Lunch	Supper	Bedtime Snack
<70	4	3	5	0
71–100	6	4	6	0
101–150	7	5	7	1
151–200	8	6	8	2
201–250	9	7	9	2
251–300	10	8	10	3
>300	12	10	12	4

Basal rate = 1.0 U/h.

Other considerations include personal issues related to pump use such as how to wear the pump with different clothing, how with special occasions, swimming, showering, personal involvement in sports activities. Pump wearers have the option of using a multiple daily insulin injection regimen for occasions when pump use is not desired.

There are three insulin pump manufacturers at present. As pump technology is constantly changing, there are general characteristics to consider when selecting a pump. These include: (1) pump size, (2) type of reservoir used, (3) power source (batteries needed), (4) ease of wear, (5) ease of programming, (6) safety features and alarm systems, (7) special features such as number of programmable basal rates, bolus recall, temporary rate options, square wave bolus options, display, and resistance to moisture, (8) warranty, (9) availability of supplies for use with pump, (10) cost, (11) level of support from the manufacturer for education and dealing with problems as they arise, and (12) record of durability over time. Implantable insulin pumps are under investigation.

Methods for Determining Initial Insulin Dosages for CSII

The insulin pump delivers insulin via a continuous basal rate plus a bolus, which is a larger amount of insulin taken before a meal. The total 24-hour basal rate is usually 40–50% of the patient's daily dose. The meal boluses can be estimated as a percentage of total daily dose as follows: breakfast, 20%; lunch, 10%; dinner, 10%; and snack, 5%.³⁷ The basal rate should generally be no more than 60% of the patient's total daily dose. If the patient has reasonable glycemic control, it is advised to take the prepump total daily dose and reduce it by 10% prior to calculating pump dosages since insulin requirements are often lower with insulin pump therapy.

For example, a starting insulin pump dose for a patient who was taking NPH 22 units and regular 8 units before breakfast, and NPH 10 units and regular 6 units before supper, for a total daily dose of 46 units, is as follows:

Basal rate: $46 \times 50\% (0.50 \times 46) \div 24 \text{ hours} = 1.0 \text{ U/h}$

Boluses: Breakfast, 9.0 units ($46 \times .20$)
Lunch, 4.5 units ($46 \times .10$)
Dinner, 7.0 units ($46 \times .15$)
Bedtime snack, 2.0 units (46×0.5)

An alternative way to calculate the total daily basal rate is to multiply the patient's weight in kilograms by 0.3. If the patient's weight was 80 kg (176 lb), the basal rate would be $(80 \times 0.3) \div 24 = 1.0 \text{ U/h}$. Assuming the basal rate was 50% of the total daily dose, the boluses would be calculated as above using 48 units as the total daily dose.

Patients using insulin pump therapy have the advantage of programming different basal rates for varying diurnal insulin needs. Patients often need lower basal rates between bedtime and 3:00–5:00 AM and higher basal rates between 3:00–9:00 AM to deal with the so-called "dawn phenomenon." An intermediate basal rate may be needed during the rest of the day. An adjustment of the basal rate by 10–20% is usually recommended. Using the example above, the basal rate profile might be as follows:

- 11:00 PM to 4:00 AM = 0.9 U/h
- 4:00 AM to 8:00 AM = 1.2 U/h
- 8:00 AM to 11:00 PM = 1.0 U/h

After calculating insulin boluses using the above formula, evaluate these starting dosages relative to the patient's meal plan. An average of 1 unit of short- or rapid-acting insulin will dispose of 10–15g of carbohydrate, with a range of 0.5–2.0 units. For a meal containing 60g of carbohydrate, a bolus dose of 4–6 units would be a reasonable place to start. Using the above example, if the breakfast meal plan consisted of 60g of carbohydrate, 9 units of short- or rapid-acting insulin might be too much and a lower starting bolus at breakfast may be indicated. Once initiated, careful blood glucose monitoring must be performed to determine the effectiveness of insulin dosages relative to the meal plan and the patient's usual activity level. Frequent adjustments in the starting insulin dose are usually required during the first 1–3 months of a new regimen.

INTENSIVE DIABETES MANAGEMENT

Intensive diabetes treatment is not simply multiple daily injections of insulin or insulin pump therapy. It is a goal-oriented, comprehensive approach to therapy that consists of frequent blood glucose self-monitoring and a systematic approach to quantifying food and matching insulin to food intake.³⁸ This treatment approach is designed to achieve near normoglycemia by enabling the patient to change aspects of the regimen as different situations are encountered through day-to-day life. Collaboration among team members including physicians, nurses, dietitians, and mental health professionals is essential.^{39,40} Intensive diabetes self-management education is not a single event, but should be integrated into the ongoing care of the patient (see Tables 29-2, 29-4).

Patient Selection

Most patients with T1DM should be given the opportunity to intensify their diabetes treatment. The manner in which this is accomplished and the intensity of the treatment plan and the treatment goals will vary depending on a careful assessment of patient capabilities, resources, personal preferences, and the presence of known risk factors. Based on the results of the DCCT, any improvement in glycemic control will result in a reduction in risk for the development and progression of microvascular complications. However, since the greatest reduction in risk for long-term diabetic complications is accrued with glycosylated hemoglobin levels near the normal range, patients and health care providers need to strive for glycemic control as close to normal as is safely possible.^{1,2}

There are patients in whom the risk:benefit ratio of intensive therapy may be less favorable.¹ The major adverse event associated with intensive diabetes treatment in the DCCT was a threefold increase in the risk for severe hypoglycemia.⁴¹ Patients who have repeated severe hypoglycemia or hypoglycemia unawareness should pursue intensive therapy slowly and cautiously. Glycemic goals may need to be modified for these patients to avoid serious sequelae related to hypoglycemia.

The DCCT did not include subjects under 13 years of age. Thus intensive therapy should be implemented with greater caution in children after carefully assessing the child's capabilities and resources. Glycemic goals for children may also need to be modified to increase the safety of the treatment. Patients with advanced complications were not included in the DCCT cohort. Patients with coronary artery disease may be at a higher risk for severe sequelae

TABLE 29-2. Intensive Diabetes Treatment

<i>Treatment plan:</i>	Multiple daily insulin injections or insulin pump therapy Blood glucose monitoring 4–7 times daily Meal planning based on a systematic approach to quantifying food and matching insulin to food intake
<i>Treatment goals:</i>	Individualized based on capabilities and risk factors Ideal glycemic goals: Before meals 70–120 mg/dL After meals <180 mg/dL Bedtime 100–130 mg/dL 3:00 AM > 70 mg/dL Glycated hemoglobin level: nondiabetic range for the assay performed
<i>Characteristics:</i>	Integrates insulin and food preferences into lifestyle practices Basic prescription that can be adjusted by the patient Liberal, flexible, adapts to changing circumstances, and allows for patient choice
<i>Patient education:</i>	Basic education initially—only what is necessary to implement the treatment plan Ongoing education is integrated into each office visit Focuses on self-care behaviors and relevant issues within the context of lifestyle practices and experiences Emphasizes patient problem solving and decision making Emphasizes a systematic approach to matching insulin, food, and exercise rather than a fixed regimen
<i>Interventions:</i>	Nursing, nutrition, behavioral, and medical interventions care provided at each office visit Once the treatment plan is prescribed, taught, and implemented, interventions become more behavioral, directed at enabling patients to follow treatment recommendations
<i>Team collaboration:</i>	Team consists of patient, nurse, dietitian, physician, and mental health professional Each member contributes equally and is part of the ongoing care of the patient; communication is open and ongoing Decisions are made jointly; a unified message is delivered to the patient

from hypoglycemia. In addition, patients with proliferative or severe nonproliferative retinopathy may be at higher risk for transiently accelerated progression of their retinopathy after the start of intensive therapy and should be followed closely by their ophthalmologists. It is unlikely that advanced complications such as renal failure will reverse with intensive therapy. In such patients, the adverse effects of intensive therapy often outweigh any potential benefit.

Once risk factors have been taken into account, the intensity of the treatment plan will depend on the patient's capabilities, motivation, and resources. Blood glucose monitoring at least four times daily is essential for intensive diabetes treatment to be implemented successfully and safely.^{38,42} The choice of multiple daily insulin injections or insulin pump will depend on the patient's personal preferences and financial resources. Patients who are reluctant to pursue intensive therapy can implement aspects of an intensive treatment plan in an incremental fashion.^{43,44} By making mutually negotiated small changes in the diabetes treatment plan, the patient can demonstrate capabilities and accept aspects of intensive therapy over time.

Methods for Adjusting Insulin Dosage

Insulin Dosage Adjustments Based on Blood Glucose Levels

Intensive treatment regimens commonly utilize insulin algorithms that adjust for premeal blood glucose levels. The algorithm in Table 29-1 assumes that a patient requires about 1.0 units of short- or rapid-acting insulin for every 50 mg/dL of blood glucose. Typically, patients require about 1 unit for every 40–50 mg/dL of blood glucose, but this varies depending on the patient's insulin sensitivity and daily insulin requirements. For example, a patient taking 20 units of insulin per day may require 0.5 units of short- or rapid-acting insulin per 50 mg/dL of blood glucose, whereas a patient taking 80 units of insulin per day may require 2 or 3 units per 50 mg/dL of blood glucose. Patients can also take a supplemental dose of rapid- or short-acting insulin to lower a high blood glucose level in the absence of food intake using the same guideline.⁴⁵ When short-acting (regular) insulin is used, taking it 45–60 minutes before a meal instead of 30 minutes may be required if the premeal blood glucose level is elevated.

If the premeal blood glucose level is below normal, patients will often wait less than 15 minutes to eat after administration of short-acting insulin to avoid further hypoglycemia. However, this approach increases the likelihood that postprandial hyperglycemia will occur. The ideal approach in this situation is for the patient to correct the hypoglycemia with a rapidly-absorbed source of carbohydrate and take the bolus or short-acting insulin injection 20–30 minutes before ingesting the meal, based on the corrected blood glucose reading. This situation does not pose a problem when rapid-acting insulin is used, since the patient can eat immediately after taking the insulin injection.

Insulin Dosage Adjustments Based on Food Intake

The American Diabetes Association prioritizes maintenance of near-normal blood glucose levels as the first goal of nutrition therapy,⁴⁶ and not necessarily meeting some ideal nutrient content. To achieve this goal, nutrition therapy must be tailored to the patient's lifestyle preferences, and patients should be taught to quantify food intake and adjust insulin for variations in food and exercise.^{47–49} No food is prohibited; sucrose and starches have similar

effects on glycemia. In addition, reasonable body weight is level of weight individuals and health care providers acknowledge as achievable and maintainable, not an ideal body weight based height and frame size.^{46,48}

Several dietary approaches can be used to assist patients quantifying food intake and plan meals. The exchange system commonly used and involves planning meals based on food groups. Healthy Food Choices is a simplified version of the exchange system. This system can be made even simpler by converting 1 exchange to what we refer to as starch equivalents.³⁷ One starch equivalent is equal to one starch, or one fruit, or one milk, or one meat, or three vegetable exchanges. Carbohydrate counting requires the patient to count grams of carbohydrate and estimate insulin dosage based on carbohydrate intake only. This system assumes relatively consistent intake of protein and fat. Total available glucose (TAG) defines foods in terms of the amount of glucose derived from foods consumed. This approach assumes that 100% of calories from carbohydrate, 50% of calories from protein, and 10% of calories from fat will contribute to blood glucose.⁴⁹ TAG is the most complicated method for estimating food intake and may not be appropriate for most patients.

On average, patients need 1 unit of short- or rapid-acting insulin for every 15 g of carbohydrate (one starch exchange) consumed. However, this can range from 0.5–2.0 units per 15 g of carbohydrate. A more precise estimate of the patient's insulin need per quantity of food can be determined when the patient achieves normal blood glucose levels while following a specific meal plan and an insulin schedule. Prior to initiating a new intensive insulin regimen, the dietitian can create a meal plan based on a patient's 3- to 4-day food record. The meal plan should accurately reflect the patient's personal preferences and should not be based on some "ideal" nutrient content. The patient should follow the meal plan for at least 1 month, until desired blood glucose levels are achieved. During this time, the patient should keep detailed food and insulin records. The food records are useful to determine if the patient understands the meal plan and is quantifying food correctly. When the patient deviates from the meal plan, the food records can be used to teach the patient how to incorporate different foods into the meal plan or how to adjust the insulin for those foods. Food records also help patients identify relationships between food intake and blood glucose levels.

When desired blood glucose levels are achieved, the information from the food and insulin records can be used to determine the insulin dose required per quantity of food. For example, if a patient's meal plan at lunch consists of one fruit exchange, one milk exchange, three bread exchanges, two meat exchanges, and two fat exchanges (72 g of carbohydrate or 6 starch equivalents), and a premeal insulin dose of 9 units of short- or rapid-acting insulin results in normal postprandial blood glucose levels, the patient requires 1 unit of insulin for every 8 g of carbohydrate or approximately 1.5 units per starch equivalent at lunch. The dosage per quantity of food can be separately calculated for breakfast and dinner, recognizing that insulin requirements may vary at different times of the day. Using this information, the patient can simply estimate the number of grams of carbohydrate or starch equivalents to be consumed at the meal and multiply by the number of units required per quantity of food. The investment of time during the first 2 months to match insulin to the meal plan and determine insulin needs per quantity of food is well worth the effort, as patients tire of the meal plan or encounter situations in which dietary intake will vary. Having a systematic approach to matching insulin to changes

in dietary intake enables patients to have flexibility and still maintain near-normal blood glucose control.

Insulin Dosage Adjustments Based on Changes in Activity

Patients must learn to make adjustments in insulin or food intake for changes in activity to keep blood glucose levels near normal and to prevent hypoglycemia. If exercise is planned, insulin dosages can be adjusted. If exercise is unplanned, ingestion of additional carbohydrate will be necessary. Blood glucose testing before, during, and after the activity is recommended to monitor the patient's response to the exercise.^{50,51} Special precautions may also be needed depending on the time of the activity. Exercise-induced hypoglycemia can occur many hours after the activity. Nocturnal hypoglycemia can actually occur in response to intense morning or afternoon exercise.^{52,53}

Premeal short- or rapid-acting insulin can be decreased 25–50% for moderate levels of planned postprandial activity. If the activity is strenuous, the patient may need additional carbohydrate along with the reduction in premeal short- or rapid-acting insulin.⁵⁴ Patients using insulin pumps can temporarily lower the basal rate approximately 20–40% for sustained periods of exercise lasting over 60 minutes. A reduction in the basal rate by 25% during post-exercise hours may be necessary to avoid postexercise hypoglycemia.⁵⁵ Suspending the basal rate for more than an hour is not recommended. For patients receiving morning NPH insulin, the morning dose of NPH may need to be reduced 15–25% for planned afternoon or evening exercise.⁵⁶ Activities such as yard work, shopping, and housework are common events in patients' lives that frequently result in episodes of hypoglycemia. Patients may need to reduce insulin and/or eat an additional snack for these kinds of activities.

If the patient engages in unplanned exercise, additional carbohydrate must be consumed. A useful guideline is to ingest 15–30 g of carbohydrate for every 30–45 minutes of moderate exercise. For sustained periods of moderate to strenuous exercise, one protein exchange prior to the exercise may also be necessary.⁵⁴ Patients also need to be reminded to replace fluids during exercise, especially for outdoor activities in warm temperatures. This is particularly true if autonomic dysfunction is present.

Blood Glucose Monitoring

Blood glucose self-monitoring is an essential component of the safe and effective implementation of intensive diabetes treatment. Blood glucose testing is most effective when the technical aspects are mastered and the results are used in a problem-solving fashion to achieve glycemic goals (see Table 29-3). Patients make decisions about elements of the treatment plan in a variety of situations based on blood glucose test results. Evaluating the effectiveness of health care recommendations or of a specific intervention depends upon self-monitored blood glucose levels. Regular and frequent blood glucose testing also provides a means to set glycemic goals and evaluate goal achievement. The patient's blood glucose records enable the patient and health care provider to identify problems and solutions. Feedback from the health care provider regarding blood glucose test results assists the patient to understand the meaning of blood glucose levels and their relationship to specific self-care behaviors.

When intensive treatment is initiated, frequent blood glucose testing before each meal, 1.5–2 hours after each meal, and at bed-

TABLE 29-3. Blood Glucose Self-Monitoring

1. Select a blood glucose meter suited to the patient's needs, abilities, resources, and personal preferences. Consider the meter's:
 - Size
 - Display
 - Ease of use
 - Dependence on user technique
 - Type of batteries
 - Calibration procedure
 - Cost
 - Manufacturer support and warranty
 - Accuracy
 - Storage capability for blood glucose results
 - Ability to interface with computer software
2. Provide technical instruction.
3. Monitor the patient's technical competence; i.e., observe technical performance and check patient-obtained results against laboratory results performed simultaneously.
4. Specify the frequency and circumstances under which blood glucose monitoring is to be performed.
5. Specify desired blood glucose targets.
6. Educate the patient on the meaning of blood glucose results; identify the relationship between blood glucose levels and self-care behaviors.
7. Specify guidelines for dealing with blood glucose levels within and outside the desired range.
8. Provide feedback regularly.

time provides a profile of fasting and pre- and postprandial glycemia that assists in making insulin dosage adjustments. Blood glucose tests at 3:00 AM several times a week assist in determining the appropriateness of basal insulin delivery or bedtime intermediate-acting insulin. Once glycemic goals have been achieved, blood glucose testing before each meal, at bedtime, and weekly at 3:00 AM is the minimum required for safe and effective intensive diabetes treatment.^{1,37,38}

Investigators have shown that a patient's blood glucose records frequently misrepresent the number of blood glucose tests performed as well as the blood glucose levels obtained.^{57,58} Meters that have the capacity to store over 100 blood glucose readings as well as the date and time the readings were obtained can be useful to facilitate reliable recordkeeping.⁵⁹ Memory meters can also interface with computers so that the data stored in the meter can be retrieved and analyzed. There are several software packages that will analyze parameters such as average blood glucose levels by time of day and day of the week, average number of blood glucose tests per day, and percentage of readings above, below, and within target ranges. Graphic representations of blood glucose readings can also be obtained. These glucose data management systems summarize blood glucose results in a way that is meaningful for patients, and help patients identify patterns and any progress they made. The statistical summaries also give health care providers tangible ways to share positive feedback with the patient, and can assist in making changes in the treatment plan and setting and evaluating glycemic goals.⁶⁰ The use of memory meters and computer-assisted glucose management can also improve glycemic control.⁶¹

New technologies may facilitate blood glucose monitoring. Several meters allow for alternate-site (e.g., the forearm) capillary blood glucose testing, and require as little as 0.3–1.0 μ L of blood. Glucose sensors are at various stages of development. A device manufactured by Minimed is currently available only to physicians, and can monitor a patient's blood glucose readings for up to 3 consecutive days. The device is worn much like a cardiac Holter

monitor. It is anticipated that the sensor used in that device will become available for patient use in the future. The sensor is composed of a microelectrode with a thin coating of glucose oxidase beneath several layers of a biocompatible membrane. An introducer needle allows for subcutaneous insertion of the sensor. Glucose is converted into an electronic signal which is transmitted via a wire that is connected to the introducer needle. The wire is attached to a monitor about the size of a beeper which records blood glucose readings every 5 minutes, providing 288 glucose readings per day. The physician can download the stored blood glucose readings to the computer for analysis.

The GlucoWatch® (Cygnus) is another sensor recently made available for patient use. Worn on the wrist like a watch, the sensor provides blood glucose readings every 20 minutes for up to 12 hours. Alarms that warn the user when blood glucose readings go below preset low or high levels can be individually set. To use the GlucoWatch, the patient slides a thin plastic sensor onto the back of the watch. An extremely low-voltage electric current pulls glucose molecules through the skin into gel pads in the sensor. The glucose reacts with glucose oxidase present in the gel pads to form hydrogen peroxide. The biosensor detects the hydrogen peroxide, generating an electronic signal which is converted into the glucose reading.

Both of these devices require at least one conventional blood glucose test per day for calibration.

Prevention and Management of Hypoglycemia

Intensive diabetes treatment designed to achieve near-normal glycemic control carries an increased risk for severe hypoglycemia,⁶¹ as well as a decrease in the signs and symptoms of hypoglycemia, causing so-called hypoglycemic unawareness.⁶² This is related to an impaired counterregulatory hormone response to hypoglycemia⁶³ and/or brain adaptation to glucose uptake at below-normal blood glucose levels.^{64,65} Recent antecedent hypoglycemia reportedly reduces autonomic and symptomatic responses to hypoglycemia.^{66,67} There is evidence that avoiding hypoglycemia restores hypoglycemic awareness in patients with T1DM.^{68,69} Education and surveillance are important in reducing the incidence and severity of hypoglycemia. Having a systematic approach to matching insulin to food intake and performing frequent blood glucose monitoring provide the foundation for implementing a treatment plan with precision, thus reducing the incidence of hypoglycemia.

Education regarding the prevention and treatment of hypoglycemia should include a discussion of the causes and symptoms of hypoglycemia. Family and friends need to be involved in learning how to recognize hypoglycemia and how to treat it, especially if the patient experiences confusion, coma, or seizure. Family members and/or friends should know how to administer a glucagon injection when patients cannot ingest oral carbohydrates without risk of aspiration. The usual adult dose of glucagon is 0.5–1.0 mg injected intramuscularly.

Treatment for mild hypoglycemia consists of 15–30 g of a rapidly absorbed source of carbohydrate such as juice, sugar-sweetened soft drinks, or commercially prepared tablets or gels. Patients should be instructed to have such sources of carbohydrate with them at all times including at the bedside, in the car, purse or briefcase, desk or locker, and gym bag, and during exercise and travel. The ingestion of carbohydrate should be repeated every 15–20 minutes until the blood glucose level has returned to normal (>70 mg/dL).

Patients need to identify changing symptoms of hypoglycemia. Instruct patients to pay close attention to how they feel when glucose levels drop below 70 mg/dL. Often patients describe sensations of weakness, emptiness, or just feeling different. When patients become aware of these vague symptoms, they can detect and treat hypoglycemia before becoming confused or lapsing into coma or seizure.

When patients exercise or deviate from their usual routine, patients should check their blood glucose levels more often to make sure that any adjustment they made in insulin or diet is appropriate. Because the frequency of nocturnal hypoglycemia is often undetected, weekly blood glucose testing at 3:00 AM may be performed to guard against hypoglycemia while the patient is sleeping. Bedtime snacks consisting of some protein and carbohydrate may be necessary to avoid nocturnal hypoglycemia.

All intensively treated type 1 diabetic patients should be instructed to check their blood glucose level before operating a vehicle. If the patient senses hypoglycemia while driving, the patient should be instructed to pull over to the side of the road, stop the vehicle, treat the hypoglycemia, and resume driving only when the blood glucose level has returned to normal. Patients should take insulin before driving without eating. When planning to eat, insulin should be taken after arriving at the restaurant.

Encourage patients to identify situations they are likely to encounter that have a high probability of resulting in hypoglycemia. Activities that have resulted in hypoglycemia in the past. Typical activities such as shopping, housework, yard work, or travel can increase the potential for hypoglycemia. Develop a plan to deal with that situation so that hypoglycemia is avoided. If an episode of hypoglycemia occurs, assist the patient in identifying the cause of the episode and tell the patient what can be done differently to avoid future episodes. If severe hypoglycemia recurs, glycemic goals may need to be modified.

Educating Patients to Implement Intensive Diabetes Treatment

Diabetes education is not only needed to provide information and training to perform skills such as insulin injections and blood glucose monitoring, but also to assist patients to integrate their regimen into their lifestyle and achieve measurable treatment goals. Health education should motivate and enable patients to change their diabetes self-management behaviors in ways that will lead to measurable improvements in glycemic control.⁷⁰ Although diabetes education is an important component of treatment,^{71,72} increased knowledge alone does not necessarily result in improved self-management behavior or glycemic control.^{73,74} Education programs that include behavioral strategies are more likely to succeed in achieving treatment goals.

The initial education required for an intensive diabetes treatment plan should include blood glucose monitoring, insulin administration, meal planning, and management of hypo- and hyperglycemia (see Table 29-4).⁷⁵ It is neither necessary nor desirable to overwhelm patients with too much information at one time. Focusing on key information until mastery of those concepts is achieved provides patients with a firm foundation upon which to build more advanced problem-solving and decision-making skills.

This initial education can be provided in a number of ways. If a slower, more incremental approach is desired, teaching patients one concept at each outpatient visit spaced at monthly or bimonthly intervals enables the patient to master the skill and demonstrate capabilities.⁴³ Matching the intervention to the patient's readiness for

TABLE 29-4. Education for Intensive Diabetes Treatment

<i>Initial Education</i>	
(3–4 outpatient visits and a 3-day inpatient hospital stay or 3–4 outpatient visits and a 3- to 7- day intensive outpatient course)	
• Blood glucose monitoring • Insulin administration • Meal planning and system for quantifying food • Management of hypoglycemia and hyperglycemia	
<i>Education and Management Post initiation</i>	
(Biweekly visits and weekly phone calls for 1–2 months)	
• Keep food and blood glucose records • Identify relationship between dietary intake and blood glucose readings • Identify problem areas and revise meal plan as needed • Educate on how to deal with specific situations • Adjust insulin dosages as needed to achieve glycemic goals	
<i>Ongoing Education and Follow-up</i>	
(Monthly for 2–6 months, then every 2–3 months)	
• Teach patient to interpret blood glucose readings • Teach patient to adjust insulin for deviations in dietary intake and activity • Identify problems with implementation of the treatment plan • Identify strategies for dealing with obstacles that interfere with implementing the treatment plan • Adapt treatment recommendations to lifestyle situations • Anticipate problems and develop strategies to prevent potential problems from interfering with achieving treatment goals	

change increases the likelihood that a desired modification in behavior will occur.⁷⁶ Patients can also be taught all of the basic intensive diabetes management skills through a 3- to 7-day course that may be conducted on either an inpatient or outpatient basis.

After the initial education is provided, frequent contact with the patient is required so the newly acquired knowledge can be reinforced as patients integrate the treatment plan into their day-to-day lives. Phone contact is recommended at least weekly during the first 1–2 months of intensive diabetes treatment. Patients can fax or send blood glucose and dietary records to assist in identifying problems and solutions.⁷⁷ Visits biweekly for 1–2 months and then monthly may be necessary until the patient has mastered treatment techniques, integrated them into activities of daily life, and achieved glycemic goals. Frequent follow-up and close supervision have been associated with improved outcomes.^{44,78,79}

Once competence in the basic skills of intensive diabetes treatment is demonstrated, patients can be taught more advanced problem-solving and decision-making skills. These skills include interpreting blood glucose levels, adjusting insulin for deviations in food intake and activity level, and dealing with a variety of situations the patient may encounter. As the patient's lifestyle changes, treatment recommendations need to be modified. The emphasis is on anticipating insulin needs for different circumstances so blood glucose levels remain within the desired range.

These skills are best taught within the context of the patient's actual experiences. Adults have a problem-centered orientation to learning, and their readiness to learn relates to immediate application of information for a specific problem they are experiencing. Ideally, education should be integrated into every office visit so that problems and solutions can be identified as the problems are encountered. Feedback should be provided soon after a solution is implemented, to determine the effectiveness of the strategy and to reinforce positive changes. New interventions should be based

on an evaluation of the relative success or failure of the previous intervention.⁸⁰

Strategies That Enhance Achieving Diabetes Treatment Goals

Diabetes treatment is complex, and is affected by most daily activities. Adherence to prescribed regimens has been reportedly as low as 12%, with diet being the most difficult component of the treatment plan to master.^{81–83} All too often health care providers blame the patient for not achieving treatment goals rather than examining the health care provider's communication style or approach to treatment recommendations that may interfere with a patient's implementation of self-management strategies.^{84–86}

Characteristics of a successful approach to intensive diabetes treatment are listed in Tables 29-2 and 29-5. The treatment regimen should be as simple as possible and match the patient's ability and lifestyle. The treatment plan should allow for flexibility and adaptability to the patient's preferences; patients should have as much choice and as many options as possible. For example, patients can fit sweets such as candy bars and doughnuts into their meal plans and/or adjust insulin for these foods to maintain desired blood glucose levels.^{87,88} The patient should be encouraged to identify and solve self-management problems, rather than told what to do in a paternalistic fashion.^{89,90}

TABLE 29-5. Strategies That Enhance Adherence to Treatment

1. Match the diet and other aspects of the regimen to the patient's current lifestyle, habits, and personal preferences.
2. Design the insulin regimen to match the patient's dietary intake.
3. Keep the treatment plan as simple as possible.
4. Do not overwhelm the patient with too much information at one time; focus on the information the patient needs to implement the treatment plan.
5. Integrate education into every office visit; teach concepts as issues arise and provide information when relevant to a specific situation or experience.
6. Create an environment in which the patient feels comfortable to be honest:
 - Allow the patient to disagree with you.
 - Respect the patients' feelings.
 - Encourage the patient to express his or her own views.
 - Incorporate the patients' views into treatment recommendations.
 - Avoid interrupting the patient.
 - Avoid being critical or judgmental.
 - Avoid an authoritative tone.
7. Allow the patient as much choice and as many options as possible; allow for flexibility.
8. Encourage the patient to be the problem solver and decision maker; ask questions so the patient will identify the solution.
9. Negotiate specific and realistic goals. Establish goals that will lead to success.
10. Assist the patient to change health care behaviors when the patient is ready; make changes one small step at a time.
11. Provide frequent opportunities for positive feedback and encouragement.
12. Help the patient to identify obstacles that can interfere with achieving treatment goals.
13. Help the patient develop a plan to minimize obstacles to implementation of treatment recommendations.
14. Use contracts to define measurable and realistic goals, as well as reward contingencies.

Health care providers also need to create an environment in which the patient feels comfortable enough to be honest. Blood glucose and food records should be viewed as information to help identify and solve diabetes management problems, and should not be used to be critical or judgmental. It is not constructive for patients to make emotional attachments to “bad” or “good” blood glucose readings. Correcting the high or low blood glucose readings is a positive way for the patient to approach blood glucose readings outside the desired range.

Removing Obstacles to Adherence

Most patients can achieve some degree of adherence if the treatment is acceptable, understandable, and manageable. If the patient is not following the treatment plan, there may be a discrepancy between the health care provider's expectations and those of the patient. If the patient's goals are different, they need to be clearly stated and/or renegotiated. If the patient is unhappy with the treatment plan, it should be changed based on an accurate assessment of the patient's needs and abilities. If the patient does not understand the treatment plan or how to carry it out, the patient needs to be reeducated. If the patient understands the treatment plan and wants to implement it, identify obstacles to following the treatment plan.⁹¹

Obstacles to adherence to a treatment plan may be intrapersonal or interpersonal, or may be related to the patient's social system or the treatment itself.⁸⁰ Intrapersonal variables that can influence adherence include the patient's emotions, level of motivation, lack of structure, financial resources, fears, values, thoughts, and beliefs. Interpersonal variables are those that influence the relationship between the patient and the health care provider. The patient may not trust or understand the health care provider or may even be angry about something the health care provider said or did. Social system variables include family pressures, beliefs, and lifestyle practices, such as grocery shopping or timing and content of meals, that are controlled by other family members. Obstacles to adherence can be related to the treatment itself, such as potential for hypoglycemia or weight gain, pain caused by obtaining capillary blood glucose readings, perceived restrictions in food intake or timing of aspects of the regimen, or lack of flexibility to suit lifestyle practices.

Once obstacles are identified, a plan to reduce those obstacles can be developed. The patient may need to verbalize beliefs and evaluate them to determine if they are logical and have importance. Misconceptions should be clarified. Misunderstandings between the patient and health care provider should be reconciled. Interpersonal problems can be prevented by establishing good rapport with patients, listening to them and validating their ideas, engaging in collaborative problem solving and decision making, allowing patients to disagree, and not blaming or criticizing patients. Involve family members in the educational process and clarify their misconceptions. Teaching patients how to talk to family members about their disease and treatment plan can also be helpful.

Treatment obstacles can be dealt with in a number of ways, and health care providers may need to be creative in assisting patients to find ways to overcome barriers to following treatment recommendations. Patients who forget to check blood glucose levels could enter blood glucose testing times into their day planner, link testing to routine daily events, or set the alarm on their watch or PDA. Patients who are making too many visits to the vending machines could leave their loose change at home. Treatment contracts are a tangible way to outline specific and achievable goals and then plan to overcome obstacles. Reinforcement contingencies specified

in the contract provide a way to give positive feedback, reimplementation of self-management strategies, and enhance patient's sense of success.

Collaboration Among Members of the Health Care Team

The behavioral and educational nature of the intervention necessary for intensive diabetes treatment requires ongoing collaboration among all of the members of the intensive diabetes management team.^{92,93} A collaborative team is one in which each member of the team contributes, including the patient. Communication is open and ongoing, opinions are freely discussed, and mutual consensus is reached. Joint decision making is the hallmark of a collaborative team. Patient satisfaction is enhanced when the patient's views are solicited, accepted, and incorporated into health recommendations.⁸⁴

An example of a collaborative team model is shown in Figure 29-7. At the center of the team is the patient. The patient is the primary problem solver and decision maker regarding day-to-day diabetes management and relies on the health care team to advise, teach, generate options, and provide support. An experienced diabetes nurse clinician, particularly one who can function as an advanced nurse practitioner, is an ideal primary health care provider for the day-to-day management of the diabetes regimen.⁹⁴ Once a plan is prescribed by the physician, the nurse and the dietitian assist the patient to learn the components of the treatment plan and integrate them into existing lifestyle behaviors. The dietitian works closely with the nurse to assess the patient's dietary practices and how they relate to blood glucose levels and insulin requirements. The nurse makes adjustments in the insulin dosage in consultation

FIGURE 29-7. The model represents collaboration among the patient and health care providers in the implementation of chronic diabetes management. The medical condition of the patient, including acute medical problems, is managed by the physician. The physician is a consultant to the chronic diabetes management team and supports the team's intervention. Once the team identifies the treatment plan, the nurse clinician becomes the primary health care provider for chronic diabetes management. The nurse and patient contribute equally in this therapeutic relationship. The patient is the primary problem solver and decision maker, and the nurse educates, advises, provides support, and helps identify problems and generate options for solving self-management problems. The dietitian and mental health professional are consulted as needed and are integrated into the ongoing follow-up of the patient. Communication is equal and ongoing among all team members, and decisions are made jointly.

COLLABORATIVE TEAM MODEL FOR CHRONIC DIABETES MANAGEMENT

with the physician or independently under physician protocol. Acute medical problems are referred to the physician, who also monitors any physical abnormalities, medications, and abnormal laboratory findings. Referrals to the mental health professional are made for psychosocial problems that interfere with diabetes self-management. Every team member contributes to the ongoing care of the patient, and education is integrated into each office visit.

SUMMARY

Intensive diabetes treatment strategies are necessary to achieve near normoglycemia and prevent or delay the long-term complications of diabetes. Intensive diabetes treatment strategies include multiple daily insulin injections or an insulin pump, frequent blood glucose monitoring, a systematic approach to quantifying food intake, matching insulin to food intake, and education that enables patients to change aspects of the regimen for varying circumstances. Intensive diabetes treatment is flexible and adaptable, and encourages the patient to be the problem solver and decision maker. Frequent feedback, ongoing education with an emphasis on behavioral interventions, and opportunities for self-monitoring and evaluation of goal achievement are important components of an intensive diabetes treatment approach. A team approach that incorporates ongoing input from nursing, nutrition, and counseling, as well as medicine, is essential to achieve measurable improvements in glycemic control. Health care providers need to inform their patients about the influence of glycemic control on the development and progression of diabetes complications, and to encourage and support every patient's efforts at implementing an intensive diabetes treatment plan.

Insulin Treatment of Type 2 Diabetes Mellitus

David M. Nathan

INTRODUCTION

The classification of diabetes mellitus into insulin-dependent or type I and non-insulin-dependent or type II diabetes mellitus, and other types, by the National Diabetes Data Group and the World Health Organization more than two decades ago provided a working model of different phenotypes of diabetes.^{1,2} The division of the diabetic population into IDDM and NIDDM was based on differences in their clinical characteristics, natural history, and presumed pathogenesis. The absolute dependence of IDDM patients on insulin therapy for survival was connoted by the “insulin-dependent” classification. Unfortunately, many clinicians continued to confuse insulin-treatment with insulin-dependence, and patients who clearly had phenotypic NIDDM, but who were treated with insulin, were often inaccurately described in medical records as having IDDM.

The most recent iteration of the nosologic classification of diabetes by the Expert Committee convened by the American Diabetes Association (ADA) added genotypic information to the classification of diabetes and refined the diagnostic plasma glucose criteria for diabetes, lowering the fasting plasma glucose threshold from 140 to 126 mg/dL.³ In addition, and in part to decrease the misclassification of patients using the old nomenclature, non-insulin-dependent diabetes mellitus was to be called type 2 diabetes (T2DM).

This chapter focuses on the insulin treatment of patients with T2DM. The population of insulin-treated T2DM patients in the U.S. is currently two to three times larger in number than the type 1 diabetic population and is growing at a rapid rate.⁴ The worldwide population of T2DM, already pandemic in nature, is projected to reach 300 million in the next 20 years.⁵ Although there have been numerous reviews of insulin therapy of type 1 diabetes,^{6–10} relatively few major reviews of insulin therapy of T2DM have appeared.^{11,12} In this chapter, I review the magnitude of the problem, the pathophysiology of T2DM as it relates to insulin treatment, the goals of therapy including the role of intensive therapy, the relative attributes of insulin therapy compared with other available treatments, the spectrum of insulin regimens and new insulins that have been tested and their relative advantages and disadvantages, the use of combination therapy, and criteria for selecting T2DM patients for insulin therapy. The treatment of T2DM patients who require insulin transiently, such as during perioperative or other stress, is not discussed in this chapter.

BACKGROUND: THE SCOPE OF THE PROBLEM

The identification of T2DM as a specific nosologic entity by the National Diabetes Data Group (NDDG) and WHO was long overdue. Despite the remarkable increase in prevalence of T2DM in the

twentieth century, it remained an underrecognized and underdiagnosed disease. The failure of patients to recognize and of clinicians to diagnose T2DM was and continues to be predicated on its subtle clinical presentation compared with type 1 diabetes. [Based on the relatively frequent appearance of long-term complications in “newly diagnosed” T2DM patients, it has been estimated that diabetes has been present for 4–7 years, on average, before it is diagnosed.¹³] T2DM was probably relatively uncommon prior to the extension of life span and the increased obesity and sedentary lifestyle that have accompanied widespread industrialization in the latter part of the twentieth century.¹⁴ The vast majority of descriptions of diabetes mellitus in the older medical literature are of type 1 diabetes, not T2DM. The historic slight against type 2 diabetes persists; even though T2DM represents as much as 90% of all diabetes mellitus, it remains “type 2” diabetes.

The spread of T2DM is reaching pandemic proportions. It currently affects 7% of the adult population in the United States, including 12% of the adult population older than 45 and almost 20% of those older than 65.^{3,15} The prevalence of T2DM is similar in Europe as in the United States. In developing countries in Asia and Africa, where T2DM has historically been relatively rare, the shift to more industrial economies with sedentary lifestyles and westernized diets has resulted in a startling increase in T2DM.^{5,14}

Currently, at least 2 million T2DM patients in the United States are treated with insulin, compared with an estimated 600,000 to 1.2 million patients with T1DM⁴ (Fig. 30-1). This represents approximately 30% of patients with diagnosed T2DM. The increasing size of the T2DM population, the disappointing long-term results with diet therapy^{16–18} (the first choice in treating the majority of T2DM patients who are obese), and the relatively high primary and secondary failure rates of sulfonylurea and metformin therapy, which are the mainstay oral hypoglycemic agents,^{18–20} strongly suggest that the fraction of the T2DM population and the total number of T2DM patients treated with insulin will increase.

PATHOPHYSIOLOGY OF T2DM: IMPLICATIONS FOR THERAPY

The pathogenesis of T2DM is multifactorial and includes decreased sensitivity to insulin action (insulin resistance) secondary to obesity and genetic factors, and decreased insulin secretion.^{21–23} While insulin resistance may be the inherited defect that accompanies most cases of impaired glucose tolerance, progressive worsening of glucose tolerance with the development of fasting hyperglycemia and T2DM is usually preceded by decreased insulin secretion.^{22,24} Fasting hyperglycemia is primarily a consequence of increased hepatic

FIGURE 30-1. Prevalence of different types of diabetes mellitus.

glucose output in the setting of relatively low insulin levels. Several studies have suggested that the impaired ability to increase insulin secretion in the face of increasing insulin resistance is also a heritable feature of T2DM.^{25,26} In addition to the decrease in insulin secretion that accompanies T2DM, the early stages of glucose intolerance are accompanied by a relatively increased secretion of proinsulin, which has less bioactivity than insulin.²⁷ Finally, the development of hyperglycemia further compromises insulin secretion and increases resistance (Fig. 30-2). This effect of hyperglycemia, termed glucotoxicity, is at least partially reversible if basal glycemia is restored to normal. The beneficial effect of achieving normoglycemia in T2DM (lower glycemia begets further improvement in glycemia with restored endogenous insulin secretion) has been demonstrated with diet, sulfonylurea, and insulin therapy.²⁸⁻³⁰

The implications of these studies with regard to therapy are the following:

1. By the time that T2DM is established, insulin secretion is relatively decreased. In some T2DM patients, the absolute level of insulin secretion may be very low. Insulin secretion as measured by basal and stimulated C-peptide levels often overlaps the levels seen early in the course of type 1 diabetes.^{31,32}
2. With longer duration, metabolic control worsens with higher glycemic levels. This is largely attributable to progressive deterioration in insulin secretion.³³
3. Residual insulin secretion in T2DM, at least early in its course, provides a degree of stability to glucose levels not present in

FIGURE 30-2. Pathophysiology of type 2 diabetes mellitus.

type 1 diabetes. Insulin regimens need not be as complex in the treatment of T2DM as in the treatment of type 1 diabetes.

4. Although T2DM patients may have severely impaired insulin secretion, they rarely become ketotic. There have been several populations identified, including an African-American population in Flatbush, Brooklyn,³⁴ and a subset of T2DM patients in Scandinavia,³⁵ that appear to be more vulnerable to the development of ketoacidosis. Whether some of these "T2DM" patients, especially in Scandinavia where the prevalence of type 1 diabetes is relatively high, are actually misdiagnosed is unclear. In any case, T2DM patients who are thin and/or ketonuric should probably be treated as if they have type 1 diabetes.
5. Correction of fasting hyperglycemia by any means has been demonstrated to result in improved insulin secretion and a modest improvement in resistance. Therapy with insulin early in the course of T2DM may result in remission for as long as several years with no need for hypoglycemic drugs and normal glycemia.³⁶
6. Ideally, suppression of increased overnight hepatic glucose output should normalize fasting blood glucose and improve endogenous insulin secretion in response to meals during the day. This effect is presumably mediated by ameliorating the toxic effects of hyperglycemia on the islets.
7. Insulin given in the morning will cover postprandial glucose excursions but may further suppress endogenous insulin secretion during the day.

METABOLIC GOALS OF THERAPY

The Diabetes Control and Complications Trial (DCCT) conclusively established blood glucose goals for type 1 diabetes.³⁷ Whether similar goals are appropriate for T2DM and the means to achieve those goals have been vigorously debated.³⁸⁻⁴⁰ The similar clinical characteristics of the microvascular and neurologic complications in type 1 and type 2 diabetes, and the similar relationship between the occurrence of long-term complications and level of glycemia demonstrated in epidemiologic studies of type 1 and type 2 diabetes, support a similar benefit in T2DM as demonstrated in the DCCT.^{41,42} Two recent clinical trials that have examined the effectiveness of glycemic control in preventing or ameliorating long-term complications in T2DM have provided definitive support for therapies aimed at normalizing glycemia in T2DM.^{18,43} The Kumamoto study⁴³ examined intensive therapy only with insulin, while the United Kingdom Prospective Diabetes Study (UKPDS) tried to establish whether any specific hypoglycemic therapy was advantageous by randomly assigning T2DM patients with relatively recent-onset disease to either sulfonylurea, metformin, or insulin therapy. The UKPDS tried to resolve the uncertainty left by the earlier University Group Diabetes Program (UGDP), which had similar goals.⁴⁴ The UGDP, conducted between 1960 and 1969, did not demonstrate a benefit of intensive therapy; moreover, treatment with sulfonylurea or phenformin was associated with excess cardiovascular mortality compared with the insulin-treated and diet-treated groups.

The UKPDS, completed almost 40 years after the UGDP, compared an "active" treatment policy with either sulfonylurea or insulin (or metformin in the obese subjects) with a dietary policy. Over 10-12 years of average follow-up, the active policy, which decreased HbA_{1c} by approximately 1% compared with the dietary policy, was associated with a 12% decreased risk for aggregate diabetes compli-

cations. The major effect was mediated through a 25% decrease in microvascular complications. In the Kumamoto study, relatively thin Japanese T2DM patients were treated either intensively or conventionally with insulin. The separation in HbA_{1c} was similar to that achieved in the DCCT, and the magnitude of the reduction in retinopathy and nephropathy also paralleled that seen in the DCCT.⁴³

In the aggregate, these studies support the use of intensive therapy, with the goal of achieving near-normal glucose levels, in T2DM. The UKPDS did not definitively establish whether any specific treatment modality was superior, owing to the use of a stepped intervention strategy, which resulted in substantial therapy crossovers.⁴⁵ Of note, the UKPDS demonstrated a seemingly inexorable worsening of metabolic control over time, which required the progressive addition of more hypoglycemic agents. Although patients should theoretically always respond to increasing doses of insulin, UKPDS physicians and patients were apparently reluctant to increase insulin to the doses necessary to maintain normal glucose levels.

COMPARISON OF INSULIN WITH OTHER AVAILABLE THERAPIES FOR T2DM

Efficacy

Short-term randomized studies of glycemic response to insulin versus sulfonylurea,^{46–50} including one that was double-blind,⁵⁰ have demonstrated only modest differences in glycemic control in the first weeks to months of therapy. The vast majority of studies that have examined and compared the metabolic benefits of diet, sulfonylurea, and insulin therapy have been short-term studies; longer-term controlled trials are few in number. Although the longest-term observational studies¹⁷ and controlled clinical trials, including the UGDP,⁴⁴ the Kumamoto study,⁴³ and the UKPDS,¹⁸ are 6–12 years in duration, they are relatively brief for a chronic disease such as T2DM. In concert, these studies demonstrate very limited long-term efficacy of diet therapy. The majority of the benefit with regard to weight loss and lowering of glycemia commonly noted in the first year is lost within 2–3 years with weight regain. In the UKPDS more than 50% of the patients with recent-onset T2DM assigned to diet therapy required subsequent reassignment to pharmacologic therapy in order to maintain even a modicum of glycemic control.¹⁸

Similarly, the lowering of glycemic levels with sulfonylureas or biguanides is transient, with as many as 50% of sulfonylurea-treated patients failing therapy, either in the first 3 months of therapy (primary failure) or after a salutary initial response (secondary failure).^{19,20} Results with either sulfonylurea or biguanides are remarkably similar. In the UGDP and UKPDS, glycemic levels were lowered from baseline for the first several years of therapy, but drifted back to baseline by years 3–5 of therapy.^{18,44} In the UKPDS, worsening metabolic control in patients originally assigned to sulfonylurea or metformin occurred despite the addition or substitution of alternative therapies in as much as 30% of the patients originally assigned to the oral hypoglycemics as glycemic levels rose over time.¹⁸ There are no comparable long-term data available with thiazolidinediones or the glitinides.

In contrast to sulfonylureas, biguanides, and thiazolidinediones, insulin has no upper dose limit and can be adjusted over time to achieve normal or near-normal glycemic levels. This attribute of insulin therapy has been demonstrated to provide lower levels of glycemia in oral agent failures⁵¹ or when intensive insulin therapy was compared with a conventional insulin regimen in the

UGDP,⁴⁴ Kumamoto,⁴³ or Veterans Administration Cooperative Study of Diabetes Mellitus (VACSDM).⁵² The dose of insulin required to achieve this benefit depends to a great extent on degree of insulin resistance (or level of obesity as a surrogate). In most studies of typically obese patients with relatively large doses ranging from 50–200 units per day (>0.65 U/kg) are required to achieve near-normal glycemia (30–1). Insulin doses had to be raised progressively from approximately 25 U/d at baseline to 90 U/d by 2 years in order to maintain stable glycemia in the VACSDM.⁵²

Interestingly, the UKPDS, the longest-term study of diet therapy, failed to demonstrate substantially lower glycemia with insulin therapy compared with the oral agents. Moreover, HbA_{1c} levels rose over time in the group assigned to diet therapy despite investigators' intent to raise insulin doses to control glycemia. In note, the progressive addition of alternative therapies, including insulin, for the patients originally assigned to oral agents, and the apparent reluctance of the UKPDS clinicians and/or patients to increase insulin doses, may explain these findings. In the UKPDS, the median insulin doses rose only modestly, from 22 U at 3 years to 34 U at 6 years, 34 U at 9 years, and 36 U at 12 years. The very obese patients (BMI >35 kg/m²) were also treated with modest doses of insulin, with median doses of 36 U at 3 years and 60 U at 12 years. These doses are substantially lower than the doses usually required to achieve near-normal glycemia in most studies (Table 30-1).

Other Effects and Adverse Events

A comparison of diet, sulfonylureas, biguanides, and insulin with regard to effects other than glucose control is shown in Table 30-1. Diet therapy has the best benefit/risk ratio, with weight loss resulting in improved lipid levels, blood pressure, and other cardiovascular risk factors. Sulfonylureas and insulin share several metabolic benefits other than glycemic control, such as a reduction in free fatty acid levels. Insulin raises HDL cholesterol more than sulfonylurea therapy.^{50,53} The frequency of severe hypoglycemia, defined in the DCCT as any episode requiring assistance, is generally low; however, modest weight gain (2–5 kg) is relatively common with insulin or sulfonylurea therapy (Table 30-1). Hypoglycemia associated with sulfonylurea use can be more prolonged and dangerous than the usually self-limited hypoglycemia seen with insulin. Finally, drug-specific complications occur.

Metformin, a relatively old drug that was developed in 1950 but did not become available in the U.S. until 1995, provides several interesting benefits. When used as sole therapy, it has potent effects similar to that of sulfonylureas, but does not appear to promote weight gain or cause hypoglycemia. The gastrointestinal side effects of bloating and diarrhea that are seen with higher doses and rapid escalation of the dose are usually transient and can be largely eliminated if doses are titrated slowly. The risk of lactic acidosis with metformin is almost nil if patients with decreased renal function, liver disease, severe congestive heart failure, and binge alcohol drinking are excluded from treatment.

The thiazolidinediones are relatively new oral hypoglycemic agents that appear to act by binding to peroxisome proliferator-activated receptor α (PPAR α) receptors and reducing insulin resistance.⁵⁴ They are relatively weak hypoglycemic agents when used alone, but are more efficacious when used in combination with other hypoglycemic medications, including insulin.^{55,56} Owing to rare but severe idiosyncratic liver toxicity, the first approved thiazolidinedione, troglitazone, had to be withdrawn from the U.S.

* Very uncommon with second-generation sulfonylureas such as glyburide and glipizide. Most common with chlorpropamide.

† Very rare with metformin (<3/100,000 treated patients).

‡ Severe idiosyncratic liver failure in approximately 1/35,000–50,000 patients treated with troglitazone (discontinued in March, 2000). Rosiglitazone and pioglitazone thought to be less likely to cause hepatic dysfunction.

market. Pioglitazone and rosiglitazone do not appear to suffer from the same problem, although fluid retention can be problematic.

The glitinides are nonsulfonylurea insulin secretagogues that have been introduced recently.⁵⁷ With a shorter half-life than the sulfonylureas, they are probably less likely to cause hypoglycemia than sulfonylureas, but need to be administered before each meal.

INSULIN THERAPY

Doses

As noted above, the dose of insulin required to normalize glycemia in T2DM is often more than 60 U/d. More obese, insulin-resistant patients invariably need more insulin. When calculated on the basis of body mass, most studies have required 0.6–1.0 U/kg. In general, insulin treatment is started with conservative doses with empiric adjustment based on glucose levels. Formulaic approaches to selecting an initial dose of insulin have been suggested, with some based on overnight insulin infusions.^{18,58} Since most T2DM patients are insulin-resistant, they can usually tolerate fairly high initial doses of insulin without hypoglycemia. On the other hand, hyperglycemia is very diet-responsive in T2DM, and if patients initiate their dietary efforts concurrently with beginning insulin use, they can develop hypoglycemia with relatively small doses. For the reasons above, suggest beginning with 10–15 U of intermediate-acting insulin, at bed or before breakfast. Alternatively, a very long-acting insulin, such as Ultralente or glargine, can be initiated in the evening. Adjustments can be made relatively quickly, guided by self-monitoring of blood glucose results.

As noted in Table 30-1, many studies attempting to normalize glycemia in T2DM have required large doses of insulin. However, when calculated on the basis of units per kilogram, these doses are only modestly higher than the range of doses used in the DCCT to treat adult T1DM intensively (0.66–0.73 U/kg).⁵⁹ The largest doses are generally required in the most obese, most resistant T2DM patients. Insulin requirements in the Pima Indians, whose body mass index—a measure of weight divided by height squared—exceeds 40, are often more than 150 units per day. Similarly high insulin requirements may be seen in very overweight patients of other racial groups. Many physicians remain uncomfortable using the high doses necessary to control glycemia in the near-normal range.

Various rules of thumb have been proposed to guide clinicians in deciding the rate at which to advance insulin doses. With the widespread availability of self-monitoring, which should be implemented in all insulin-treated patients, such rules have been made relatively obsolete. The results of insulin adjustments can be monitored by the patient and the rate and magnitude of further adjustments determined on the basis of self-monitoring. The decision when to split insulin from a single daily dose to two or more doses can also be guided by the results of self-monitoring. For those patients who cannot master self-monitoring, the relative stability of glycemia in T2DM makes possible monitoring of glycemia by visiting nurses or in the office setting to guide adjustment of doses. Timed glucose levels, fasting and/or before dinner, are most useful.

Regimens

Although many insulin treatment regimens have been tried (Table 30-3), most studies achieving glycemic control in the near-normal range, albeit for relatively brief periods of time, have done so with one or two daily insulin injections (Table 30-1). The UKPDS,

TABLE 30-3. Insulin Regimens for Type 2 Diabetes

Morning intermediate*
Bedtime intermediate or very long-acting
Morning intermediate + rapid†
Morning intermediate + rapid‡ with bedtime intermediate
Morning and predinner intermediate and rapid†
Dinner and or morning long-acting (Ultralente) with rapid
Morning and bedtime intermediate and prebreakfast and predinner (multiple daily injection—MDI)
Evening Ultralente with premeal rapid (MDI)

Premeal inhaled insulin with bedtime intermediate
Bedtime intermediate with morning sulfonylurea, or daily metformin, thiazolidinedione, or α -glycosidase inhibitor (combination therapy)

* Intermediate-acting: NPH or Lente.

† Rapid-acting: CZI (regular) or lispro (very-rapid acting).

‡ May be administered as premixed (e.g., 70:30 NPH/regular insulin).

which failed to maintain stable glycemia with its intensive regimen, perhaps owing to inadequate dosing, used a regimen based on a once-per-day Ultralente™ or NPH insulin supplemented with regular insulin as needed.¹⁸ The VACSDM employed increasingly complex regimens based on glycemia.⁵² In order to maintain stable glycemia over a 30-month follow-up, 64% of the subjects were advanced to two or three daily injections of insulin by study's end. Whether single injections of intermediate- or long-acting insulin or larger doses will perform as well as split doses has not been adequately studied, but is unlikely.

There are surprisingly few data available on the best timing of the injection. Conventionally, insulin therapy is initiated with morning intermediate-acting insulin, with or without rapid-acting insulin. Predinner intermediate-acting insulin, again with or without rapid-acting insulin, or prebedtime intermediate-acting insulin can be added as needed. As with intensive therapy in type 1 diabetes, the choice of doses of rapid-acting (CZI), or very-rapid-acting (lispro or aspart), insulin before meals is dictated by the results of self-monitoring of blood glucose. However, since blood glucose levels in T2DM are much less labile than in type 1 diabetes, probably mediated by endogenous insulin secretion, frequent adjustment of insulin is less necessary.

The use of nocturnal insulin has been championed^{60–62} on the basis of its ability to suppress overnight glucose output and not inhibit endogenous secretion in response to meals; however, there are few studies to recommend it over the more conventional morning regimens.⁶² Nevertheless, it is reasonable to initiate insulin therapy with intermediate-acting insulin at bedtime, adjusting the dose until fasting blood glucose levels are in the therapeutic range. This strategy can normalize fasting glucose levels and HbA_{1c} levels.⁶³ If blood glucose levels during the day remain elevated, morning intermediate-acting insulin, with or without rapid- or very-rapid-acting insulin, can be added. Premixed insulins such as 70:30 or 50:50 mixtures of NPH and rapid-acting or 75:25 mixtures of NPH and very-rapid-acting insulins are available. These mixtures are relatively stable, preserving the individual time action profiles of the components, and can be used in T2DM where day-to-day insulin doses remain relatively stable.

The use of long-acting insulin has also been espoused as a means of supplementing basal endogenous insulin without exogenous peaks which might suppress endogenous secretion.⁶⁴ Unfortunately, “peakless” beef-pork Ultralente insulin is no longer

available, and human Ultralente insulin has different absorption characteristics that may be problematic.⁶⁵ In addition, the relatively long half-life of Ultralente insulin is undesirable when dietary intake is suddenly decreased, for example with hospitalization, when rapid changes in insulin treatment may be required. The UKPDS used human Ultralente insulin.¹⁸ A new insulin analog, glargine, has similar performance characteristics as the old beef-pork Ultralente insulin, with a long half-life and no apparent peak.⁶⁶ In clinical trials, it has had little benefit compared with once- or twice-per-day NPH.⁶⁷

Other more complicated regimens including continuous subcutaneous insulin infusion (CSII) with an external pump have been used.^{28,29,68–71} Whether they are ever necessary or advantageous compared with less complex regimens is unknown. A crossover study between premeal rapid-acting insulin and twice-per-day (before breakfast and dinner) intermediate-acting insulin revealed no significant benefit of the more frequent injection regimen.⁷² Implantable insulin pumps delivering insulin either intravenously at a single rate⁷³ or by the intraperitoneal route with multiple basal rates and premeal boluses⁷⁴ have been used to treat patients with T2DM. The glycemic control was in the near-normal range in these studies, and noteworthy for the relatively low incidence of hypoglycemia. This latter finding has been typical for intensive insulin treatment in T2DM (Table 30-1) regardless of mode of therapy, in contrast to intensive regimens in type 1 diabetes, which are accompanied by a relatively high risk of hypoglycemia (60–100 episodes/100 patient-years).^{37,75} Finally, pulmonary delivery of aerosolized insulin before each meal has been used in type 2 diabetes in conjunction with an evening injection of intermediate-acting insulin.⁷⁶ The metabolic goals of this “proof of principle” study were modest. Whether long-term therapy with inhaled insulin can achieve and maintain near normoglycemia, and whether such therapy is safe, is unknown.⁷⁷

Intermittent, or short-term, intensive insulin therapy has been tested in clinical studies.^{28,29,36} The rationale behind this approach is to lower glycemia to the normal range and, by eliminating glucotoxicity, improve endogenous insulin secretion and decrease insulin resistance. After days to weeks of such therapy, insulin treatment is withdrawn. Glucose levels have been maintained at a near-normal range for as long as 2–3 years. These remissions have been demonstrated most reliably in relatively new onset T2DM.

COMBINATION THERAPY

Insulin has been used in combination with virtually every other therapeutic modality. Conventionally, diet and exercise recommendations accompany insulin therapy. In addition, combination therapy with sulfonylurea (Bedtime Insulin Daytime Sulfonylurea) has also been espoused.^{78–80} The rationale behind combination therapy is that nocturnal insulin therapy suppresses overnight glycemia and morning short-acting sulfonylurea stimulates endogenous insulin. The only potential benefit of combining insulin and sulfonylurea, which is more expensive than using insulin alone, is a modest reduction in insulin doses required to achieve a similar level of glycemia.⁷⁹ The modest (and lack of additive) effects of combined insulin and sulfonylurea are not surprising since they work by similar mechanisms, i.e. providing increased insulin. I do not favor the use of this two-drug regimen, where compliance may be lower, drug interactions more likely, and expense greater, when insulin alone in adequate doses is effective.

Other combination regimens, using drugs with different primary mechanisms of action than insulin, such as metformin or thiazolidinediones, have been examined. Most studies have not provided for aggressive adjustment of insulin in the insulin-only arm; thus, whether any benefits that occur when oral agents are added are unique to combination therapy, or whether similar results might be obtained merely by adjusting insulin, has not been conclusively established. The glycosidase inhibitor acarbose will lower HbA_{1c} levels achieved with insulin alone by 0.5%.⁸¹ The thiazolidinediones (with most data available using the troglitazone, which is no longer available) can lower HbA_{1c} when added to insulin or maintain HbA_{1c} with lower doses of insulin.⁵⁵ Only rarely does thiazolidinedione therapy allow insulin-treated patients to stop their insulin therapy. The use of metformin with insulin has also been investigated. Although HbA_{1c} levels are only modestly lower with additional metformin, weight gain is less with this combination therapy.⁸² Whether the added expense, need for additional monitoring of renal and hepatic function (for metformin and thiazolidinediones), the potential for added toxicity and drug interactions, and decreased compliance associated with combination therapy are merited by the modest improvements in HbA_{1c}, and limited weight gain (with metformin) is not clear.

HOW TO SELECT T2DM PATIENTS FOR INSULIN THERAPY

As noted above, patients who have evidence of severe insulin deficiency and a catabolic state on the basis of ketonuria, profound weight loss, or dehydration, or who are thin, should be treated as if they have T1DM (Table 30-4). This will protect such patients from more profound metabolic decompensation if, in fact, they have type 1 diabetes, and will rapidly restore all of them to a safe metabolic state. Although criteria based on fasting and stimulated C-peptide levels have been proposed to help identify such patients, the majority of them can be identified on the basis of the clinical criteria listed above. In addition, patients who are symptomatic from hyperglycemia and have not responded initially, or have failed to respond after preliminary success with diet and/or sulfonylurea or metformin, should be treated with insulin. Finally, patients with very elevated triglyceride levels who are at risk for pancreatitis should be treated with insulin and diet, rather than with an oral hypoglycemic agent, as the most effective way to rapidly lower the abnormal lipid levels.

The implications of the UKPDS¹⁸ and Kumamoto⁴³ studies are that insulin should be started in T2DM patients whose level of glycemia is not in the near-normal range with diet and/or oral agents, regardless of the presence of symptoms. In the past, clini-

TABLE 30-4. Indications for Insulin Therapy in Type 2 Diabetes Mellitus

Presence of ketonuria in unstressed state
Nonobese with persistently elevated glucose levels
Uncontrolled weight loss and hyperglycemia
Dehydration secondary to glycosuria and unresponsive to diet and/or oral agents
Severe hypertriglyceridemia
Diet or oral agent failure with or without symptomatic hyperglycemia
Hyperglycemia with aim of obtaining near-normal glycemia and/or inducing remission

cians have generally implemented stepped intervention of T2DM in a relatively unaggressive fashion, reserving insulin as a last resort, and often after patients had diabetes for many years and had established complications. The now demonstrated beneficial effects of tight control of T2DM and the recognition that dietary and oral agent interventions are, in many cases, temporizing at best, with progressive worsening of metabolic control over time, suggest that insulin treatment should be implemented earlier and aggressively in the course of T2DM. Moreover, reports of "remissions" of T2DM with early and intensive insulin therapy suggest that insulin should be considered as an early, rather than an end-stage, treatment.³⁶

CONCLUSIONS

Insulin is the most efficacious pharmacologic treatment for patients with diabetes. The long-awaited approval of metformin in the United States, and the introduction of new agents, such as the glycosidase inhibitors and the thiazolidinediones, are unlikely to decrease the need for insulin in many of the T2DM population, which is rapidly becoming the most common chronic disease in the world. Insulin is ultimately a more powerful drug than any of the other available treatments for T2DM, as well as the only naturally occurring substance used to treat it, and until the high failure rate with diet and oral agents can be abrogated, its frequent use is all but assured.

The anticipated benefits of achieving normoglycemia in T2DM, as in T1DM, should stimulate health care providers and patients alike to use the therapy that provides glycemic control as close to the nondiabetic range as safely possible. When dietary efforts fail, insulin may well be considered the most likely therapy to achieve and maintain those levels of glycemia that are likely to prevent and/or delay long-term complications. Although the best regimen for insulin use in T2DM has yet to be firmly established, a large number of permutations have been investigated. Insulin therapy, with adequate doses and in concert with careful attention to reducing all cardiovascular risk factors, should remain a mainstay of T2DM therapy.

Hypoglycemia in Type 1 Diabetes Mellitus: The Interplay of Insulin Excess and Compromised Glucose Counterregulation

Philip E. Cryer

John E. Gerich

SUMMARY

Iatrogenic hypoglycemia is the limiting factor in the glycemic management of diabetes. It is the result of the interplay of therapeutic insulin excess and compromised glucose counterregulation—the clinical syndromes of defective glucose counterregulation and hypoglycemia unawareness—at least in type 1 diabetes mellitus (T1DM). Aggressive attempts to achieve glycemic control increase the risk of severe hypoglycemia about threefold in T1DM, but it is possible to minimize that risk by (1) application of the principles of modern therapy (patient education and empowerment, frequent self-monitoring of blood glucose, flexible insulin regimens, individualized glycemic goals, and ongoing professional guidance and support) and (2) the practice of hypoglycemia risk reduction. Conventional risk factors for hypoglycemia, based on the premise that absolute or relative therapeutic insulin excess is the sole determinant of risk, include insulin excess (dose, timing, and type), decreased food ingestion, increased exercise, other drugs including alcohol, and increased sensitivity to or decreased clearance of insulin. But these explain only a minority of episodes of severe hypoglycemia. More potent risk factors that are clinical surrogates of compromised glucose counterregulation include (1) absolute insulin deficiency (indicating that the first physiological defense against falling glucose levels, a decrease in insulin levels, is lost and implying that the second defense, an increase in glucagon secretion, is also lost) and (2) a history of severe hypoglycemia or aggressive therapy *per se* as evidenced by lower glycemic goals or lower hemoglobin A_{1c} levels, the former indicating and the latter implying recurrent iatrogenic hypoglycemia. Recent antecedent hypoglycemia reduces autonomic responses (including epinephrine, the third defense against falling glucose levels) and symptomatic responses (which normally prompt the behavioral defense) to subsequent hypoglycemia. This is the basis of the concept of *hypoglycemia-associated autonomic failure* in T1DM, which posits that episodes of iatrogenic hypoglycemia cause hypoglycemia unawareness and, in the setting of absent glucagon responses and a defective glucose counterregulation, lead to a vicious cycle of recurrent hypoglycemia. Indeed, as little as 2–3 weeks of scrupulous avoidance of iatrogenic hypoglycemia reverses hypoglycemia unawareness and, at least in part, the reduced epinephrine component of defective glucose counterregulation in most af-

ected patients. Thus while hypoglycemia is a problem for people with diabetes that has not been solved and needs to be addressed vigorously both clinically and investigatively, the goal of improving glycemic control and minimizing hypoglycemia are not incompatible.

THE CLINICAL PROBLEM

Hypoglycemia is the limiting factor in the glycemic management of diabetes mellitus both conceptually and in practice.^{1,2} Were it not for the potentially devastating effects of hypoglycemia, diabetes would be rather easy to treat. Administration of enough insulin (or any effective drug) to lower plasma glucose concentrations to or below the normal range would eliminate the symptoms of hyperglycemia and prevent diabetic ketoacidosis or hyperosmolar coma, almost assuredly prevent the long-term specific complications of diabetes (retinopathy, nephropathy, and neuropathy), and likely reduce atherosclerotic risk. But the effects of hypoglycemia on the brain are real, and the management of diabetes is therefore complex.

It is now well established that glycemic control makes a difference for people with diabetes. It prevents or delays the specific long-term complications.^{3,4} Nonetheless, over a mean of only 6.5 years diabetic retinopathy developed or progressed in 14% (100 of 711) of patients with T1DM treated intensively (compared with 32% of those treated conventionally) in the Diabetes Control and Complications Trial (DCCT).³ Similarly, nephropathy and neuropathy developed or progressed in many patients treated intensively (albeit again at lower rates than in those treated conventionally). The occurrence of these complications of diabetes in a substantial portion of people with diabetes over a rather short period of time, despite aggressive attempts to lower circulating glucose levels was largely, perhaps exclusively, the result of the inability to achieve euglycemia in the vast majority of patients. Fewer than 5% of those treated intensively maintained normal hemoglobin A_{1c} levels (<6.05%). The median hemoglobin A_{1c} was 7.2% and mean ($\pm$ SD) capillary blood glucose levels were 155 ± 30 mg/dL, approximately twice those of nondiabetic individuals. Euglycemia could not be achieved safely in the vast majority of the patients because of the barrier of iatrogenic hypoglycemia. The

incidence of severe hypoglycemia (that requiring the assistance of another individual) was more than threefold higher in the patients treated intensively. Clearly, even under the optimized conditions of the DCCT, hypoglycemia was the limiting factor in the management of T1DM. As shown in the United Kingdom Prospective Diabetes Study, that is also the case late in the course of type 2 diabetes mellitus (T2DM).^{4,5} Over time, during intensive therapy of T2DM, hypoglycemia became limiting,⁵ median hemoglobin A_{1c} levels rose to approximately 8.1%, and complications occurred (e.g., any microvascular endpoint in 8% compared with 11% in the conventional therapy group).⁴

THE CLINICAL CONTEXT

Glycemic control is a fundamentally important component of the management of diabetes.^{3,4} The detection and treatment of hypertension, elevated LDL-cholesterol levels, and incipient nephropathy, retinopathy, and neuropathy, and the provision of comprehensive preventive and therapeutic care are also fundamentally important.⁶ But the challenge of achieving and maintaining improved glycemic control safely is the focus of this chapter.

Because of the barrier of hypoglycemia, sustained euglycemia is an unrealistic goal for the vast majority of people with T1DM^{1,3,7} (and for many with T2DM^{1,5}). Aggressive attempts at glycemic control increase the risk of severe, at least temporarily disabling, iatrogenic hypoglycemia (i.e., that requiring the assistance of another individual) more than threefold in T1DM. That was documented in both of the controlled clinical trials with sample sizes large enough to demonstrate beneficial effects of intensive therapy with respect to the long-term complication of diabetes, namely the DCCT^{3,7} and the Stockholm Diabetes Intervention Study.^{8,9} It was confirmed in a meta-analysis that also included 12 smaller controlled trials of intensive therapy.¹⁰ The key word here is *controlled*. The fact that aggressive attempts to achieve near euglycemia in T1DM increase the risk of iatrogenic hypoglycemia, documented in controlled clinical trials,^{3,7,8-10} cannot be negated by reports of uncontrolled series with seemingly low rates of severe hypoglycemia.

Nonetheless, it is possible to reduce the risk of hypoglycemia during aggressive therapy of T1DM. That too was demonstrated in the DCCT. During the feasibility phase of the DCCT the rate of severe hypoglycemia was about sixfold higher in the intensive therapy group compared with the conventional therapy group.^{7,11} During the subsequent full scale trial, that was reduced to about threefold.^{3,7} As discussed later, minimizing the risk of hypoglycemia in people with T1DM involves both application of the principles of modern aggressive therapy and consideration of the roles of both therapeutic insulin excess and compromised physiological and behavioral defenses against developing hypoglycemia.

THE PHYSIOLOGY OF GLUCOSE COUNTERREGULATION

Systemic Glucose Balance

Glucose is an obligate metabolic fuel for the brain under physiological conditions.¹ This is in contrast to other organs that can oxidize fatty acids as well as glucose. Because of its unique dependence on glucose, and because it cannot synthesize glucose or store more than a few minutes' supply as glycogen, the brain requires a

continuous supply of glucose from the circulation. Facilitated diffusion of glucose from the blood to the brain is a direct function of the arterial plasma glucose concentration. At normal plasma glucose concentrations, the rate of blood-to-brain glucose transport exceeds the rate of brain glucose metabolism. However, as the arterial plasma glucose concentration falls below the physiological range (approximately 70–110 mg/dL [3.9–6.1 mmol/L] in the postabsorptive state) blood-to-brain glucose transport becomes limiting to brain energy metabolism, and thus to survival. Given the immediate survival value of maintenance of the plasma glucose concentration, it is not surprising that physiological mechanisms that prevent or rapidly correct hypoglycemia have evolved. Indeed, these are so effective that hypoglycemia is a distinctly uncommon clinical event except in people who use drugs that lower plasma glucose levels (e.g., insulin, sulfonylureas, or alcohol).¹

Normally, rates of endogenous glucose influx into the circulation and those of glucose efflux out of the circulation into tissues other than the brain are coordinately regulated, largely by the plasma glucose-lowering (regulatory) hormone insulin and the plasma glucose-raising (counterregulatory) hormones glucagon and epinephrine, such that systemic glucose balance is maintained, hypoglycemia (as well as hyperglycemia) is prevented, and a continuous supply of glucose to the brain is assured.¹ This is accomplished despite wide variations in exogenous glucose influx (e.g., after feeding compared with during fasting) and in glucose efflux (e.g., during exercise compared with during rest). Hypoglycemia occurs when rates of glucose appearance in the circulation (the sum of endogenous glucose production, from the liver via both glycogenolysis and gluconeogenesis, and to a lesser extent from the kidneys via gluconeogenesis,¹² and of exogenous glucose delivery from ingested carbohydrates) fail to keep pace with rates of glucose disappearance from the circulation (the sum of ongoing brain glucose metabolism and of variable glucose utilization by tissues such as muscle and fat, as well as the liver and kidneys, among others).

Falling plasma glucose concentrations normally elicit a typical sequence of responses. Arterialized venous glycemic thresholds for several of these¹³⁻¹⁵ are listed in Table 31-1. Insulin secretion decreases (favoring increased glucose production as well as decreased glucose utilization by tissues other than the brain) as plasma glucose levels decline within the physiological range. Secretion of counterregulatory hormones including glucagon (which stimulates hepatic glycogenolysis and gluconeogenesis) and epinephrine (which stimulates hepatic glycogenolysis and gluconeogenesis and renal gluconeogenesis¹⁶ and limits glucose utilization by insulin-sensitive tissues) as well as both cortisol and growth hormone (both of which limit glucose utilization and support glucose production) increases as plasma glucose levels fall just below the physiological range. Lower plasma glucose levels cause symptoms and signs of hypoglycemia, and ultimately brain dysfunction.

When the same quantitative method (i.e., the hyperinsulinemic stepped hypoglycemic clamp technique coupled with hyperinsulinemic euglycemic clamps in the same individuals on a separate occasion) is used, the glycemic thresholds for the various responses to falling plasma glucose concentrations in healthy subjects are quite reproducible from laboratory-to-laboratory.¹³⁻¹⁵ Nonetheless, these thresholds are dynamic rather than static. They shift to higher plasma glucose concentrations in people with poorly controlled diabetes (who often have symptoms of hypoglycemia at higher-than-normal glucose levels) and to lower plasma glucose

concentrations in people who suffer recurrent hypoglycemia, such as those with well-controlled diabetes or with an insulinoma (who often tolerate subnormal glucose levels without symptoms), as discussed later.

Clinical Manifestations of Hypoglycemia

Symptoms of hypoglycemia can be divided into two categories: neuroglycopenic and neurogenic (or autonomic) symptoms.¹⁷ Neuroglycopenic symptoms are the direct result of CNS neuronal glucose deprivation. They include behavioral changes, confusion, fatigue, seizure, loss of consciousness, and if hypoglycemia is severe and prolonged, death. Neurogenic symptoms are the result of the perception of the physiological changes caused by the autonomic nervous system discharge triggered by hypoglycemia. They include adrenergic symptoms such as palpitations, tremor, and anxiety, and cholinergic symptoms such as sweating, hunger, and paresthesias. Adrenergic symptoms are mediated by epinephrine released from the adrenal medullae and norepinephrine released from sympathetic postganglionic neurons, the adrenal medullae, or both. Cholinergic symptoms (at least sweating) are thought to be mediated by acetylcholine released from sympathetic postganglionic neurons.

Common signs of hypoglycemia include pallor and diaphoresis. Heart rate and the systolic blood pressure are typically raised, but these findings may not be prominent. To the extent they are observable, the neuroglycopenic manifestations are often valuable, albeit nonspecific, signs. Transient focal neurological deficits occur occasionally. Permanent neurological damage is uncommon.

Normal Glucose Counterregulation

The principles of glucose counterregulation are as follows. First, the prevention and the correction of hypoglycemia involve both waning of insulin and activation of glucose counterregulatory factors. These are not due solely to dissipation of insulin. Second, whereas insulin is the dominant plasma glucose-lowering factor, there are redundant glucose counterregulatory factors. There is a fail-safe system that prevents failure of the counterregulatory process even when one, or perhaps more of the components of the system fails. Third, there is a hierarchy among the counterregulatory factors. Some are more important than others. The fact that there is a hierarchy of redundant glucose counterregulatory factors

that normally prevent or rapidly correct hypoglycemia is assuredly a reflection of the survival value of the preventive sustained hypoglycemia throughout evolution.

The physiology of glucose counterregulation¹ is also summarized in Table 31-1. The first defense against falling plasma glucose concentrations is decreased insulin secretion. Among the counterregulatory factors, glucagon plays a primary role. Glucose recovery from hypoglycemia is impaired and postabsorptive plasma glucose concentrations decline, but then plateau when glucagon is deficient. Although demonstrably involved, epinephrine is normally critical, but it becomes critical when glucagon is deficient. Hypoglycemia develops or progresses when both glucagon and epinephrine are deficient and insulin is present, regardless of the actions of the other glucose counterregulatory factors. Thus insulin, glucagon, and epinephrine stand high in the hierarchy of redundant glucose counterregulatory factors. Growth hormone and cortisol, both of which tend to raise plasma glucose concentrations over several hours, are involved in defense against prolonged hypoglycemia. However, neither is critical to recovery from even prolonged hypoglycemia or to prevention of hypoglycemia after overnight fast.^{1,18} There is some evidence that glucose autoregulation—endogenous glucose production as an inverse function of ambient glucose levels independent of hormonal and neural regulation—is involved, albeit only during very severe hypoglycemia.¹ Other hormones, neurotransmitters, or substrates other than glucose may also be involved, but if so they play minor roles.

THE PATHOPHYSIOLOGY OF GLUCOSE COUNTERREGULATION IN DIABETES

Frequency and Impact

Because of the imperfections of all current insulin replacement regimens, coupled with compromised physiological and behavioral defenses against falling plasma glucose concentrations as discussed later, people with T1DM are at ongoing risk for episodes of hypoglycemia.¹ Those attempting to achieve glycemic control suffer untold numbers of episodes of asymptomatic hypoglycemia (plasma glucose levels may be lower than 50 mg/dL [2.8 mmol/L] as much as 10% of the time) and an average of two episodes of symptomatic hypoglycemia per week. They suffer an episode of severe, at least

TABLE 31-1. Physiological Responses to Decreasing Plasma Glucose Concentrations

Response	Glycemic Threshold* (mg/dL)	Physiological Effects	Role in the Prevention or Correction of Hypoglycemia (Glucose Counterregulation)
↓ Insulin	80–85	↑ R_a (↓ R_d)†	Primary glucose regulatory factor; first defense against hypoglycemia
↑ Glucagon	65–70	↑ R_a	Primary glucose counterregulatory factor; second defense against hypoglycemia
↑ Epinephrine	65–70	↑ R_a , ↓ R_d	Involved, critical when glucagon is deficient; third defense against hypoglycemia
↑ Cortisol and growth hormone	65–70	↑ R_a ; ↓ R_d	Involve, not critical
Symptoms	50–55	↑ Exogenous glucose	Prompt behavioral defense (food ingestion)
↓ Cognition	<50	—	Compromises behavioral defense

*Arterialized venous, not venous, plasma glycemic thresholds in healthy individuals, 13–15.

† R_a , rate of glucose appearance, glucose production by the liver and kidneys.

R_d , rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle (the glucoregulatory hormones have no direct effect on CNS glucose utilization).

temporarily disabling hypoglycemia, often with seizure or coma, in a given year. Although seemingly complete recovery from the latter is the rule, the possibility of persistent cognitive deficits has been raised and permanent neurological defects can occur. It has been estimated that about 2–4% of deaths of people with T1DM are the result of hypoglycemia.^{1,20} In addition, hypoglycemia can cause recurrent or even persistent psychosocial morbidity. The reality of hypoglycemia, the rational fear of hypoglycemia, or both can preclude true glycemic control in T1DM.

Overall, hypoglycemia is a substantially less frequent problem in T2DM.¹ However, it occurs during treatment with sulfonylureas and other insulin secretagogues (and has been reported in patients treated with metformin) or insulin, and its frequency approaches that in T1DM in those who reach the insulin-deficient end of the spectrum of T2DM.⁵ In one series the frequency of severe hypoglycemia was similar in patients with T2DM and T1DM matched for duration of insulin therapy.²¹ The United Kingdom Prospective Diabetes Study investigators concluded that over time, hypoglycemia becomes limiting in the treatment of T2DM just as it is in the treatment of T1DM.⁵

Altered Glucose Counterregulation in Diabetes

Glucose counterregulation is altered fundamentally in all people with established (i.e., C-peptide negative) T1DM.¹ It is defective in most, and is often associated with unawareness of hypoglycemia.¹

As the person with T1DM becomes absolutely insulin deficient over the first few months or years of clinical T1DM, circulating insulin levels become totally unregulated; they are a passive function of administered insulin. Thus insulin levels no longer fall as glucose levels fall. The first defense against hypoglycemia is lost. Furthermore, within the same time frame the glucagon response to falling glucose levels, the second defense, is also lost.^{22,23} The mechanism of this selective and therefore functional rather than anatomic defect in glucagon secretion is unknown, although it is closely linked to, and potentially attributable to, absolute insulin deficiency.²⁴ In most patients the third defense against hypoglycemia is compromised when the epinephrine response to hypoglycemia is reduced.^{23,25–27} In contrast to the absent glucagon response, the reduced epinephrine response is mainly a threshold abnormality; an epinephrine response can be elicited, but lower plasma glucose concentrations are required.²⁷ This functional threshold shift is largely the result of recent antecedent hypoglycemia, as discussed shortly, although there may well be an additional anatomic component in patients affected by classic diabetic autonomic neuropathy.^{28,29} Thus established T1DM is not just an insulin-deficiency state. From the perspective of defense against hypoglycemia, it is an insulin, glucagon, and epinephrine deficiency state.

The development of an attenuated epinephrine response to falling glucose levels is a critical pathophysiological event. Patients with T1DM who have combined deficiencies of their glucagon and epinephrine responses have the clinical syndrome of *defective glucose counterregulation*,¹ and have been shown in prospective studies to suffer severe hypoglycemia at rates 25-fold or greater higher than those with absent glucagon but intact epinephrine responses during aggressive therapy.^{30,31}

Hypoglycemia unawareness is loss of the largely (if not exclusively) neurogenic warning symptoms of developing hypoglycemia that previously prompted the patient to act (e.g., to eat) to abort the episode. Thus the first manifestation of a hypoglycemic episode is neuroglycopenia, and it is often too late for the patient to recognize and self-treat the episode. Hypoglycemia unawareness is

also largely the result of recent antecedent hypoglycemia, as discussed shortly. Reduced β -adrenergic sensitivity has also been reported.³² It too has been shown in prospective studies to be associated with a high frequency of severe iatrogenic hypoglycemia.³³

Recent antecedent hypoglycemia reduces autonomic (including adrenomedullary epinephrine) and symptomatic responses (among others) to subsequent hypoglycemia—it actually shifts the glycemic thresholds for these responses to lower plasma glucose concentrations—in nondiabetic individuals^{34–38} and in patients with T1DM.^{27,39,40} It also impairs physiologic defense against hypoglycemia during hyperinsulinemia in patients with T1DM.²⁷ Such findings led to the formulation⁴¹ and experimental verification^{27,42–45} of the concept of hypoglycemia-associated autonomic failure in T1DM.

The concept of *hypoglycemia-associated autonomic failure* in T1DM (Fig. 31-1) posits that (1) periods of relative or absolute therapeutic insulin excess in the setting of absent glucagon responses lead to episodes of iatrogenic hypoglycemia; (2) these episodes, in turn, cause reduced autonomic (including adrenomedullary) responses to falling glucose concentrations on subsequent occasions; and (3) these reduced autonomic responses result in both reduced symptoms of developing hypoglycemia (i.e., hypoglycemia unawareness) and—because epinephrine responses are reduced in the setting of absent glucagon responses—impaired physiological defense against developing hypoglycemia (i.e., defective glucose counterregulation). Thus a vicious cycle of recurrent hypoglycemia is created and perpetuated.

Perhaps the most compelling support for the concept of hypoglycemia-associated autonomic failure in T1DM is the finding in three independent laboratories^{42,46,47} that the syndrome of hypoglycemia unawareness, and at least in part the reduced epinephrine component of the syndrome of defective glucose counterregulation, is reversible after as little as 2 weeks of scrupulous avoidance of iatrogenic hypoglycemia in affected patients with T1DM. While this involves a shift of glycemic thresholds for symptoms, and for the epinephrine response back toward higher plasma glucose concentrations, the basic mechanisms of hypoglycemia-associated autonomic failure remain to be established. Evidence that it is mediated by the cortisol response to previous hypoglycemia^{48,49} and involves increased brain glucose uptake^{50,51} has been presented although the latter has been challenged.⁵²

Consistent with the concept of hypoglycemia-associated autonomic failure, recent antecedent hypoglycemia also shifts glycemic thresholds for cognitive dysfunction during hypoglycemia to lower plasma glucose concentrations,^{43–45} and impairs detection of hypoglycemia in the clinical setting in patients with T1DM.⁴⁴ In addition to shifting the thresholds for adrenomedullary (plasma epinephrine) and parasympathetic (plasma pancreatic polypeptide) responses, it has been reported to reduce the sympathetic neural response to subsequent hypoglycemia.^{38,48,49}

CLINICAL RISK FACTORS FOR HYPOGLYCEMIA IN THE CONTEXT OF THE PATHOPHYSIOLOGY OF GLUCOSE COUNTERREGULATION

The conventional risk factors for iatrogenic hypoglycemia in T1DM, those with which people with diabetes and their caregivers deal regularly, are based on the premise that absolute or relative therapeutic insulin excess—which must occur from time to time because of the pharmacokinetic imperfections of all current insulin

Hypoglycemia-Associated Autonomic Failure

FIGURE 31-1. Schematic diagram of the concept of hypoglycemia-associated autonomic failure in type 1 diabetes.

replacement regimens—is the sole determinant of risk. These risk factors include insulin doses that are excessive, ill-timed, or of the wrong type; decreased food intake; exercise; drugs including alcohol; and increased sensitivity to or decreased clearance of insulin, and are detailed in Table 31-2. However, it became clear early in the DCCT that these conventional risk factors explain only a minority of episodes of severe iatrogenic hypoglycemia.¹¹ Indeed, in a multivariate model none was a statistically-significant risk factor. Clearly we must look beyond these to understand the majority of episodes.

Iatrogenic hypoglycemia is more appropriately viewed as a result of the interplay of absolute or relative therapeutic insulin excess and compromised glucose counterregulation—compromised physiological and behavioral defenses against developing hypoglycemia—at least in T1DM¹ (Table 31-2). Three clinically well-documented risk factors for iatrogenic hypoglycemia that are statistically more potent than the conventional risk factors are (1) absolute insulin deficiency (i.e., C-peptide negativity);^{7,24,53} (2) a his-

tory of severe hypoglycemia;^{7,53} and (3) aggressive therapy *per se* as evidenced by lower glycemic goals or lower hemoglobin A_{1c} levels.^{7,53} These are clinical surrogates of compromised glucose counterregulation, the clinical syndromes of defective glucose counterregulation and hypoglycemia unawareness, and the pathophysiologic construct of hypoglycemia-associated autonomic failure.

Absolute endogenous insulin deficiency indicates that plasma insulin concentrations—which are then simply the result of passive absorption of exogenous insulin—cannot decrease as plasma glucose concentrations fall. Furthermore, absolute insulin deficiency accurately predicts that plasma glucagon levels will not increase as plasma glucose concentrations fall.²⁴ Thus C-peptide negativity, a potent clinical marker of increased risk of severe hypoglycemia in T1DM, indicates that the first two physiological defenses against developing hypoglycemia—decrease in insulin and increase in glucagon—are lost. Therefore, the patient is dependent upon the third physiological defense, increases in epinephrine.

TABLE 31-2. Conventional Risk Factors for Hypoglycemia in Diabetes

1. Insulin doses excessive, ill-timed, or of the wrong type
2. Decreased influx of exogenous glucose (during the overnight fast or following missed meals or snacks)
3. Increased insulin-independent glucose utilization (during exercise)
4. Decreased endogenous glucose production (alcohol, other drugs, renal failure)
5. Increased sensitivity to insulin (following exercise; middle of the night, with glycemic control; with increased fitness, weight loss, or both; drugs)
6. Decreased insulin clearance (renal failure)

But this third physiological defense (along with the behavioral defense prompted by symptoms) is compromised in patients with the other clinical markers of increased risk: severe hypoglycemia, a history of severe hypoglycemia or aggressive therapy *per se* as evidenced by lower glycemic goals, and lower hemoglobin A_{1c} levels (a history of hypoglycemia indicating an aggressive therapy implying recurrent episodes of antecedent hypoglycemia). As discussed earlier, hypoglycemia begets hypoglycemia by reducing the autonomic (including epinephrine) and symptomatic responses to subsequent hypoglycemia, thus causing the syndromes of defective glucose counterregulation (reduced epinephrine responses in the setting of absent glucagon responses), and hypoglycemia unawareness (reduced neurogenic symptom responses). This is hypoglycemia-associated autonomic failure in T1DM.

These concepts were developed in people with T1DM. The extent to which they apply to those with T2DM remains to be established critically. It appears that they also apply to patients with relatively long-standing, insulin-requiring T2DM, and in keeping with this, hypoglycemia becomes limiting to glycemic control in such patients.⁵

Hypoglycemia Risk Reduction

Hypoglycemia is a fact of life for people with T1DM (and some with T2DM) who attempt to achieve glycemic control.^{3-5,7-11,53} Given the shortcomings of all current insulin replacement regimens, including the most sophisticated regimens available, it is not practical to both maintain euglycemia and eliminate episodes of asymptomatic and even symptomatic hypoglycemia in T1DM. That awaits the ultimate goal of the prevention and cure of diabetes or, probably in the shorter term, development of clinical strategies for perfect or near perfect insulin replacement coupled with measures that prevent, correct, or compensate for compromised glucose counterregulation.² Nonetheless, every effort must be made to minimize the risk of hypoglycemia, and eliminate the risk of severe hypoglycemia, while pursuing the greatest degree of glycemic control that can be achieved safely in an individual person with diabetes.

To practice hypoglycemia risk reduction, an approach conceptually analogous to cardiovascular risk reduction, we must first address the issue of hypoglycemia in every patient contact. In addition to asking about episodes of hypoglycemia—and assessing the patient's awareness of developing hypoglycemia—and looking for low values in the patient's self-monitoring of blood glucose (SMBG) log, it is important to determine the extent to which the patient is concerned about the reality or the possibility of hypoglycemia. Fear of hypoglycemia can be a barrier to glycemic control.

The second step in hypoglycemia risk reduction is application of the principles of modern aggressive therapy: patient education

and empowerment, frequent SMBG, flexible insulin replacement regimens, rational individualized glycemic goals, and ongoing professional guidance and support. Successful management of diabetes, particularly glycemic management, is accomplished by a well-informed and empowered patient who receives comprehensive preventive and therapeutic medical care.

The third step in hypoglycemia risk reduction is consideration of both the conventional risk factors for iatrogenic hypoglycemia (Table 31-2) that lead to episodes of absolute or relative therapeutic insulin excess (insulin doses, timing and type, patterns of food ingestion and of exercise, interactions with alcohol or other drugs, and altered insulin sensitivity to or clearance of insulin) and the risk factors for compromised glucose counterregulation that impair physiological and behavioral defenses against developing hypoglycemia (Table 31-3). The principle is that iatrogenic hypoglycemia is the result of the interplay of insulin excess and compromised glucose counterregulation rather than insulin excess alone.

The clinical surrogates of risk attributable to compromised glucose counterregulation include absolute insulin deficiency (which may be apparent from a history of ketosis-prone diabetes requiring insulin therapy from the time of diagnosis, although it is now recognized that insulin deficiency can sometimes develop more gradually) and a history of recurrent hypoglycemia or, absent that, lower glycemic goals, lower hemoglobin A_{1c} levels, or both. It is possible to test for defective glucose counterregulation (with a low-dose insulin infusion test^{30,31}), but that is generally not practical. On the other hand, a diagnosis of hypoglycemia unawareness can be made from the history. Clinical hypoglycemia unawareness (which also implies defective glucose counterregulation) is a strong clue to recurrent antecedent hypoglycemia whether or not that has been documented. In the future, documentation will become increasingly possible as continuous glucose monitoring systems become available.

Obviously, with a history of recurrent hypoglycemia, one should identify when it occurs and adjust the treatment regimen accordingly. With a basal-bolus insulin regimen, morning fasting hypoglycemia implicates the long- or intermediate-acting insulin, daytime hypoglycemia implicates the rapid- or short-acting insulin, and nocturnal hypoglycemia may implicate either, all in the context of the other risk factors for insulin excess (Table 31-2). Notably, substitution of preprandial rapid-acting (e.g., lispro or aspart) for short-acting (regular) insulin reduces the frequency of nocturnal hypoglycemia.⁵⁴ Similarly, substitution of longer-acting basal insulins (e.g., glargine) for NPH or ultralente insulin may reduce nocturnal hypoglycemia.

A history of severe iatrogenic hypoglycemia—that requiring assistance from another individual—is a clinical red flag. Unless it was the result of an obviously remediable factor, such as a missed meal after insulin administration or vigorous exercise without the appropriate regimen adjustment, a substantive change in the regi-

TABLE 31-3. Risk Factors for Hypoglycemia in Diabetes

1. Absolute or relative therapeutic insulin excess (the conventional risk factors)	
2. Compromised glucose counterregulation	
• Absolute insulin deficiency (C-peptide negativity)	
β-Cell destruction:	No ↓ in insulin response to ↓ glucose
Unknown:	No ↑ in glucagon in response to ↓ glucose
• History of severe hypoglycemia or aggressive therapy <i>per se</i> (lower glucose goals, lower HbA _{1c})	
Episodes of hypoglycemia:	Attenuated autonomic (including ↑ epinephrine) activations and symptoms in response to ↓ glucose (defective glucose counterregulation and hypoglycemia unawareness)
• Hypoglycemia-associated autonomic failure	

men must be made. If it is not, the risk of recurrent severe hypoglycemia is unacceptably high.^{7,53}

A history of hypoglycemia unawareness implies recurrent hypoglycemia. If that is not apparent to the patient or to his or her family or from the SMBG log, it is probably occurring during the night. Indeed, hypoglycemia, including severe hypoglycemia, occurs most commonly during the night in people with T1DM.^{7,11} That is typically the longest interdigestive interval and time between SMBG and the time of maximal sensitivity to insulin.⁵⁵ Furthermore, sleep often precludes recognition of warning symptoms of developing hypoglycemia and thus the appropriate behavioral response, and has been reported to further reduce the epinephrine response to hypoglycemia and thus further compromise physiological defense against developing hypoglycemia.⁵⁶ Current approaches to the problem of nocturnal hypoglycemia include regimen adjustments, including use of rapid-acting insulin during the day, and administration of bedtime snacks, although the efficacy of the latter is largely limited to the first half of the night.⁵⁷ Experimental approaches include bedtime administration of uncooked cornstarch,^{58,59} the glucagon-releasing amino acid alanine, or the β_2 -adrenergic agonist terbutaline.⁵⁷

The value of uncooked cornstarch is controversial. While Ververs and colleagues⁵⁸ using hourly blood sampling found that bedtime administration of a snack that included 0.2–0.8 g/kg body weight of uncooked cornstarch (the equivalent of 14.0–56.0 grams in a 70-kg individual) did not prevent nocturnal hypoglycemia (symptoms, blood glucose <54 mg/dL [3.0 mmol/L], or both) in young T1DM subjects, Kaufman and Devgan⁵⁹ reported reduced (as compared to controls) episodes of self-monitored low (<60 mg [3.3 mmol/L]) blood glucose (SMBG) levels at 0200h in young T1DM subjects given a snack that included 5.0–15.0 grams of uncooked cornstarch for 14 days. Thus it remains to be established that bedtime administration of only 5.0 grams of cornstarch (the dose, apparently limited by palatability, in preparations available commercially) would consistently reduce the frequency of hypoglycemia throughout the entire night. Bedtime administration of alanine (with glucose) or terbutaline has been shown to prevent nocturnal hypoglycemia more effectively than a conventional bedtime snack.⁵⁷ The limited solubility of alanine in the dose used (40 g) limits its practicability. While bedtime terbutaline can cause metabolic effects (slightly higher lactate, nonesterified fatty acid and perhaps β -hydroxybutyrate levels) and hemodynamic effects (higher heart rates) during the night that are undesirable at least in theory, and can cause hyperglycemia the following morning,⁵⁷ the convenience and flexibility of tablet dosing make it an attractive option when other approaches to the problem of nocturnal hypoglycemia are unsuccessful.

Given clinical hypoglycemia unawareness, a 2–3 week period of scrupulous avoidance of hypoglycemia is advisable, and can be assessed by return of awareness.^{42,46,47} While this can be accomplished without^{46,47} or with minimal⁴² compromise of glycemic control, this outcome required substantial involvement of health professionals. In practice it might involve acceptance of somewhat higher glucose levels over the short term. Nonetheless, with the return of symptoms of developing hypoglycemia, empirical approaches to better glycemic control can then be tried.

CONCLUDING COMMENTS

Clearly, hypoglycemia is a problem for most people with T1DM (and some with T2DM) that has not been solved. It is now well established that comprehensive treatment reduces morbidity and

mortality in people with diabetes. Comprehensive treatment includes glycemic control that at a minimum prevents or delays the specific long-term complications of diabetes^{3,4} to the extent that can be accomplished with relative safety. Aggressive attempts at glycemic control increase the risk of iatrogenic hypoglycemia, but it is possible to minimize that risk by applying the principles of modern aggressive therapy and practicing hypoglycemia risk reduction. Thus the goals of improving glycemic control and minimizing hypoglycemia are not incompatible.

Acknowledgments The authors gratefully acknowledge the contributions of their several colleagues who shaped the work that led to the views expressed in this chapter, the assistance of the staffs of our General Clinical Research Centers in the performance of our studies, and the assistance of Ms. Karen Muehlhauser in the preparation of this manuscript. The Oral Antidiabetic Agents

Sunder Mudaliar

Robert R. Henry

Type 2 diabetes (T2DM) is a chronic disease characterized by hyperglycemia and numerous other metabolic abnormalities. This disabling metabolic disorder affects more than 16 million people in the United States¹ and more than 150 million people worldwide.² Three major pathophysiologic abnormalities are associated with T2DM: impaired insulin secretion, excessive hepatic glucose output, and insulin resistance in skeletal muscle, liver, and adipose tissue.³ The treatment goals are the alleviation of symptoms through normalization of blood glucose levels and the prevention of acute and long-term complications.⁴ These goals can be achieved through pharmacologic and nonpharmacologic means. Nonpharmacologic measures include diabetes education and life-long diet management, exercise, and weight loss. Although diet and exercise remain the cornerstones of treatment, in the vast majority of patients with T2DM, pharmacologic agents are invariably needed to achieve optimal glycemic control and reduce the incidence of microvascular and possibly macrovascular complications, as shown in the United Kingdom Prospective Diabetes Study (UKPDS).⁵

Four major classes of oral pharmacologic agents are available for treatment. They act as follows at the major sites of defects in T2DM: (1) by increasing insulin availability (the secretagogues, i.e., sulfonylureas and meglitinides); (2) by suppressing excessive hepatic glucose output (the biguanides, i.e., metformin); (3) by improving insulin sensitivity (thiazolidinediones or glitazones, i.e., rosiglitazone and pioglitazone); and finally (4) by delaying gastrointestinal glucose absorption (the α -glucosidase inhibitors acarbose and miglitol) (Fig. 32-1). The therapeutic objectives recommended by the American Diabetes Association (ADA) include fasting plasma glucose (FPG) 80–120 mg/dL, bedtime plasma glucose 100–140 mg/dL, and glycosylated hemoglobin (HbA_{1c}) < 7%⁴ (Table 32-1). All of the above agents are effective as monotherapy in suitable patients and help to maintain optimal glycemic control in the initial stages. However, since T2DM is a progressive disease, over a period of time glycemic control inevitably deteriorates, and eventually combination oral therapy or (in many patients) insulin therapy will be needed to achieve optimal glycemic levels. This was clearly demonstrated in the UKPDS.⁵ Here we review the pharmacology, mode of action, and clinical applications of the various antidiabetic agents alone and in combination.

INSULIN SECRETAGOGUES

The insulin secretagogues have potent hypoglycemic effect through stimulation of insulin secretion from the pancreatic β cell. This class of agents includes the sulfonylureas and the meglitinides.

Sulfonylureas

Sulfonylureas have been available for the treatment of T2DM since the 1950s. They continue to be used as initial pharmacologic therapy, particularly when hyperglycemia is pronounced and evidence of impaired insulin secretion is present. Furthermore, sulfonylureas are often the foundation of combination therapy because of their ability to increase or maintain insulin secretion. They have a long history of use and few serious side effects (including hypoglycemia) and are relatively inexpensive. The major disadvantage is secondary failure, which may occur with all oral agents due to the progressive nature of T2DM. Placebo-controlled studies have shown that sulfonylureas reduce FPG levels by about 54–72 mg/dL and HbA_{1c} levels by 1.5–2% in patients with long-standing T2DM.^{6–8}

Although all sulfonylurea antidiabetic agents exhibit similar hypoglycemic mechanisms, there are quantitative differences in their individual pharmacokinetic properties that distinguish them. Chlorpropamide, acetohexamide, tolazamide, and tolbutamide are classified as first-generation agents, and glyburide, glipizide, and glimepiride as second-generation agents. In Europe and other parts of the world, glibenclamide and gliclazide are marketed as the equivalent of glyburide and glipizide. Second-generation agents like glyburide and glipizide are thought to bind nonionically to plasma proteins; the first-generation sulfonylureas are thought to bind by both ionic and nonionic mechanisms.^{9,10} *In vitro*, acidic drugs such as warfarin and aspirin displace sulfonylureas with ionic binding to a much greater extent than sulfonylureas with non-ionic binding. It was once thought that these differences in binding might cause certain agents such as glyburide to have a better drug interaction profile than some of the other sulfonylureas. This has not been proved clinically. A list of the sulfonylureas is given in Table 32-2.

TABLE 32-1. Goals for Glycemic Control

Biochemical Index	Normal	Goal	Action Suggested
Fasting/preprandial plasma glucose (mg/dL)	<110	80–120	<80 or >140
Bedtime plasma glucose (mg/dL)	<120	100–140	<100 or >160
Glycosylated hemoglobin (%) (normal range 4–6)	<6	<7	>8

FIGURE 32-1. The major sites of action of the various classes of oral antidiabetic agents.

Mechanism of Action

The hypoglycemic action of the sulfonylureas is due to stimulation of ATP-dependent K^+ channels (K_{ATP} channels) in the pancreatic islet cells (Fig. 32-2). When sulfonylureas bind to the receptors, they close these K_{ATP} channels. This results in a decrease in K^+ permeability of the β -cell membrane, depolarizes the membrane, and opens voltage-dependent Ca^{2+} channels, leading to an increase in intracellular calcium.¹¹ The calcium ions bind to calmodulin, resulting in the exocytosis of insulin-containing secretory granules. Recently, it has been demonstrated that the K_{ATP} channel is a complex of a 140-kd sulfonylurea receptor (SUR) and an inward rectifier channel protein (KIR6.2).¹² The K_{ATP} channels

are also inhibited by glucose and other islet ATP-generating fuels.¹³ Sulfonylureas can increase insulin secretion at substimulatory concentrations of glucose, suggesting an enhancement of β -cell response, and when β cells are exposed to maximally effective glucose concentrations, demonstrating an additive effect independent of glucose concentrations.¹³ Incidentally, ATP-dependent K^+ channels binding sulfonylureas are also present in the myocardium, vascular smooth muscle, adipose tissue, and brain, in addition to the β cell. The role of these receptors in vascular and cardiac tissue is discussed below; the significance of sulfonylurea binding in the brain remains to be defined.

Prolonged administration of the sulfonylureas may also produce extrapancreatic effects that contribute to its hypoglycemic activity. These effects include reduction of basal hepatic glucose production and an enhanced peripheral sensitivity to insulin secondary to intracellular signaling events that follow insulin receptor binding. The relative importance of each of these actions to the overall therapeutic effect of the drugs varies among sulfonylureas and from patient to patient. Although a main effect of sulfonylureas appears to be stimulation of basal insulin secretion, these antidiabetic agents also stimulate the secretion of insulin throughout the duration of a meal.¹³

All the sulfonylureas bind to the same receptor site, and differences in potency may relate, in part, to differences in binding affinity. Sulfonylureas also vary widely in their rates of absorption, bio-transformation, and elimination, all of which account for the differing potencies and dosages of the various agents in this class. These drugs are not effective in the absence of functioning β cells, as occurs in T1DM, or when the number of viable β cells is low, as occurs in those with long-standing T2DM.

TABLE 32-2. First- and Second-Generation Sulfonylurea Compounds

Name	Initial Dose (mg/day)	Daily Dose Range (mg/day)	Recommended Maximum Daily Dose (mg/day)	Doses/Day
First generation				
Tolbutamide	500–1500	500–3000	3000	2–3
Chlorpropamide	100–250	100–500	500	1
Tolazamide	100–250	100–1000	1000	1–2
Acetohexamide	250–500	250–1500	1500	1–2
Second generation				
Glyburide	1.25–2.50	1.25–20	20	1–2
Micronized formulation	0.75–1.50	0.75–12	12	1
Glibenclamide	1.25–2.50	1.25–2.50	20	1–2
Glipizide	2.5–5	2.5–40	40	1–2
Glipizide XL	5	5–20	20	1
Gliclazide	40	40–320	320	1–2
Glimepiride	1–2	4–8	8	1

FIGURE 32-2. Sulfonylureas bind to receptors (Sur) on the β -cell membrane, cause decreased permeability of K^+ channels, and depolarize the membrane. This causes the voltage-dependent Ca^{++} channels to open, leading to an increase in intracellular calcium and the exocytosis of insulin-containing secretory granules. The K_{ATP} channel is a complex of a 140-kd sulfonylurea receptor (Sur) and an inward rectifier channel protein (Kir 6.2). The Sur subunit contains unique binding sites for glyburide and repaglinide.

Pharmacokinetics

All the sulfonylureas are rapidly absorbed from the GI tract after oral administration. The pharmacokinetics and metabolism of the sulfonylureas are shown in Table 32-3. It is noteworthy that the half-life of chlorpropamide is very long, ranging from 25–60 hours, with a duration of action of 24–72 hours.

Clinical Use and Efficacy

Sulfonylureas have been used as oral hypoglycemic agents for approximately 50 years,¹⁴ and despite the availability of multiple classes of oral agents, these drugs continue to be used frequently as initial pharmacologic therapy, particularly when hyperglycemia is pronounced and evidence of impaired insulin secretion is present. Furthermore, because of their ability to increase or maintain insulin secretion, these agents are often the foundation of combination therapy. Placebo-controlled studies have shown that sulfonylureas reduce FPG levels by about 54–72 mg/dL in patients with long-

standing T2DM.^{6–8} The plasma glucose-lowering effect is slightly better in patients who have been recently diagnosed.⁶ Glycosylated hemoglobin levels are reduced on the average of 1.5–2% with use of these agents.^{6–8}

Although similar in efficacy to first-generation agents (tolbutamide, chlorpropamide, tolazamide, and acetohexamide), second-generation sulfonylureas (glyburide, glipizide, and glimepiride) are more potent and lack some of the side effects seen with older agents. As a result, they have largely replaced first-generation agents in the clinical setting. Of the second-generation sulfonylureas available, two formulations (glipizide extended release and glimepiride) have the convenience of maximum effectiveness with once-a-day dosing and the potential for greater long-term compliance. Glipizide extended release (Glucotrol XL®) provides controlled release of the short-acting sulfonylurea. Once-daily administration provides effective control of plasma glucose concentrations throughout the 24-hour dosing interval, with less peak-to-trough fluctuation than conventional glipizide.⁸ A multicenter, open-label, randomized, two-way crossover study⁸ demonstrated that extended-release glipizide is as effective as conventional glipizide in lowering postprandial plasma glucose levels but is significantly more effective in reducing FPG levels than conventional glipizide at week 8 of treatment. In addition, extended-release glipizide exerts its glycemic effect at lower insulin and C-peptide levels, which suggests enhanced insulin sensitivity. Extended-release glipizide lowers HbA_{1c} levels and both fasting and postprandial glucose over a dose range of 5–60 mg/day, with maximal efficacy achieved at a dose of 5 mg for HbA_{1c} and 20 mg for FPG.¹⁵

The second-generation agent glyburide is also available in a micronized (smaller particle size) formulation (Glynase® PresTab® tablets) that offers improved bioavailability over conventional glyburide and can be administered once or twice daily. A 12-week double-blind, randomized trial demonstrated no significant differences in glycemic or glycosylated hemoglobin levels between patients receiving 5-mg tablets of original glyburide versus 3-mg tablets of micronized glyburide.¹⁶ However, because of the difference in bioavailability, patients should be retitrated when they are switched from original to micronized glyburide. The incidence of side effects is similar for the two agents.

Glimepiride (Amaryl®) is the most potent sulfonylurea on a per-milligram basis and appears to be as effective as other sulfonylureas in reducing glucose levels when administered at 1–8 mg daily.^{7,17,18} Glimepiride, like other sulfonylureas, can be used alone

TABLE 32-3. Metabolism of Sulfonylureas

Compound and Date of Introduction	Biologic Plasma Half-Life (h)	Duration of Hypoglycemic Action (h)	Mode of Metabolism	Activity of Metabolites	Excreted in Urine (%)
Tolbutamide	4–6.5	6–10	Hepatic carboxylation	Inactive	100
Chlorpropamide	36	60	Hepatic hydroxylation or side chain cleavage	Active	80–90
Tolazamide	7	12–14	Hepatic metabolism	Three inactive	85
Acetohexamide	4–6	12–18	Hepatic reduction to 1-hydroxyhexamide	2.5 × original	60
Glyburide (glibenclamide)	4–11*	24	Hepatic metabolites	Mostly inactive	50
Glipizide	2.5–4.7	Up to 24	Hepatic metabolites	Inactive	50
Gliclazide	8–11	Up to 24	Hepatic metabolites	Probably inactive	60–70

*Micronized in 4 hours.

Source: Data from Gerich,⁹ Groop,¹⁰ and Zimmerman.¹⁴

or in combination with other anti-hyperglycemic agents. It is also the only sulfonylurea approved for use as an adjunct to insulin therapy. Maximal efficacy is achieved at 4–8 mg daily.⁷ In clinical studies, once-daily doses of 1–8 mg significantly reduced FPG by 43–74 mg/dL and HbA_{1c} values by 1.2–1.9% compared with placebo.¹⁸ In 1-year clinical studies, although glimepiride was similar in efficacy to glibenclamide and glipizide, it appeared to reduce blood glucose more rapidly than glipizide over the first few weeks of treatment. There is now preliminary evidence that although all sulfonylureas bind to the same ATP-dependent K⁺ channels, glimepiride exhibits different binding behavior to these channels, particularly in the heart (discussed later). Thus, in one study, compared with glibenclamide, glimepiride was able to maintain ischemic myocardial preconditioning during balloon angioplasty.¹⁹

Since they have potent insulin secretory effects, primary failure of sulfonylurea therapy is uncommon if patients are carefully selected. It is possible that some patients failing sulfonylurea therapy have unrecognized T1DM.²⁰ When recognized, these patients should always be treated with insulin. Secondary failure of sulfonylurea therapy is also a major long-term therapeutic problem and seems to relate mainly to the natural history of T2DM and decreasing β -cell function. The incidence of secondary failure is also difficult to ascertain since its definition varies from study to study, but it is generally reported to range from 5 to 10% per year.²¹ There have been suggestions that the secondary failure of sulfonylureas may be due to exhaustion of the pancreatic β cells. This hypothesis, however, has no evidence to support it. In the UKPDS, β -cell deterioration occurred at the same rate in diet-treated, metformin-treated, and sulfonylurea-treated patients.²² It appears difficult to identify clinical features predicting secondary failure to sulfonylureas.²³ The primary predictive factor appears to be the duration of diabetes. Studies conducted to see whether a temporary reduction in hyperglycemia with insulin therapy restores the effectiveness of sulfonylurea therapy have not been successful.^{24,25} Patients who fail to achieve ADA target goals should be started on combination therapy with any of the other oral agents or on insulin.

Extrapankreatic Effects

Over time, patients with T2DM who are treated with sulfonylureas have an improvement in β -cell function and a reduction of insulin resistance. However, it is known that improvement of hyperglycemia by other treatment methods also results in similar improvements in β -cell function and insulin resistance. Thus it is possible that the improvement is nonspecific and the result of a reduction of glucose or metabolic toxicity rather than a direct effect of sulfonylureas.²⁶ Even so, interest persists in possible extrapancreatic effects of sulfonylureas because, during chronic sulfonylurea therapy, acute insulinotropic actions appear to be reduced.²⁷

The sulfonylureas possess extrapancreatic effects that have been studied both *in vitro* and *in vivo*, in animal and human studies.²⁸ In rat L6 cultured skeletal muscle cells, tolazamide enhances glucose uptake by increasing the number of functioning cellular glucose transport molecules by 70%.²⁹ Glyburide has also been shown to stimulate glucose transport in cultured L6 muscle cells by a protein kinase C-mediated pathway that requires new protein synthesis. In this study, the authors speculated that although intracellular Ca²⁺ metabolism may be involved in this process, the initial step in the mechanism of action is probably different between pancreatic β cells and muscle cells.³⁰ In isolated insulin-resistant rat adipocytes, glimepiride activates glucose transport by stimu-

lation of GLUT-1 and GLUT-4 translocation via interference at a site downstream of the putative molecular defect in the signaling cascade between the insulin receptor and the glucose transport system induced by high concentrations of glucose and insulin. This molecular site of glimepiride action is related to GLUT-4 phosphorylation/dephosphorylation.³¹ Glimepiride also increases cardiac glucose uptake in isolated rat cardiomyocytes, by an insulin-independent pathway most probably involving an increased protein expression of GLUT-1 and GLUT-4.³²

In human studies, Prigeon and colleagues³³ in their study in 15 patients with T2DM found that glyburide treatment did not have any effect on peripheral glucose uptake, as measured by the insulin sensitivity index. On the other hand, Beck-Nielsen and colleagues³⁴ demonstrated that sulfonylurea treatment of obese patients with T2DM enhances insulin-stimulated peripheral glucose utilization in both adipose tissue and skeletal muscle, in part through a potentiation of insulin action on adipose tissue glucose transport and lipogenesis and skeletal muscle glycogen synthase. Recently, Shi and coworkers³⁵ have demonstrated that human adipocytes express a sulfonylurea receptor (SUR1) that regulates intracellular calcium and controls lipogenesis and lipolysis.

Cardiac Effects

Ever since the results of the University Group Diabetes Program (UGDP) study were published, there has been controversy regarding the potentially harmful cardiac effects of sulfonylureas.³⁶ In the UGDP, approximately 1000 patients with T2DM were randomized to diet and either placebo, tolbutamide, phenformin, standard-dose insulin, or a variable-dose insulin regimen. Unexpectedly, in 1969, after 7 years of follow-up, the tolbutamide arm was discontinued because of an observed and unexpected increase in cardiovascular and all-cause mortality.³⁷ There was widespread criticism of this study, which included insufficient patient characterization for baseline cardiovascular risk factors (e.g., cigarette smoking), as well as methodologic and interpretive problems in the study protocol.³⁸ Even so, the UGDP results fueled the longstanding controversy related to the potentially harmful cardiac effects of sulfonylurea drugs.³⁹ This is because the myocardium K_{ATP} channels mediate ischemic preconditioning, which is critical to myocardial protection and limitation of infarct size.^{40–42} These channels are normally closed; they open during ischemia in an adaptive response that protects the myocardium and induces vasodilation. Sulfonylurea binding to the channels has been shown to inhibit the response to ischemia, potentially delay the recovery of contractile function, and increase infarct size during a myocardial infarction.^{41,42} In a recent study, sulfonylurea therapy was associated with an increase in in-hospital mortality among patients undergoing direct angioplasty for myocardial infarction.⁴³

On the other hand, several studies have reported no link between long-term sulfonylurea use and increased mortality.^{44–48} The UKPDS clearly documented that long-term sulfonylurea therapy is not associated with increased cardiovascular morbidity or mortality.⁵ A recent study from the Mayo Clinic⁴⁷ did not find increased long-term mortality over 8.4 years in a group of 102 T2DM patients treated with either insulin or sulfonylureas at the time of admission to hospital with an acute myocardial infarction.

To add to the controversy further, it is known that the prevention of K_{ATP} channel opening during ischemia reduces potassium efflux from myocardial cells and also reduces the occurrence of ventricular fibrillation during ischemia.^{49–52} Indeed, in a recent study from Europe, sulfonylurea therapy was actually associated

with reduced postinfarct morbidity and mortality in patients with diabetes.⁴⁸ It is also possible that the increased cardiovascular risk may not be a class effect with sulfonylureas. There is a variable efficacy with which sulfonylurea drugs inhibit cardioprotective K_{ATP} channels. In experimental animals, inhibition of the cardiac K_{ATP} channel with glibenclamide has been shown to increase ischemia-reperfusion damage,⁵³ whereas gliclazide, a sulfonylurea with pronounced *in vivo* antioxidative properties, prevented such damage.⁵⁴ In blood flow studies in the human forearm, significant interaction with the vascular K_{ATP} channel was found for glibenclamide, whereas the effect was much less pronounced for tolbutamide⁵⁵ and even absent for the new drug glimepiride.⁵⁶ In a recent survey from Australia, glibenclamide-treated patients had significantly less ventricular fibrillation than those receiving gliclazide or insulin.⁵⁷

Thus, the interaction between sulfonylurea drugs and K_{ATP} channels during metabolic stress is complex, with various factors governing sulfonylurea-inhibitory gating of the channel.^{58,59} The net clinical effects of the seemingly opposing myocardial actions of sulfonylureas may not be deleterious.⁶⁰ Further, the UKPDS has clearly documented that long-term sulfonylurea treatment is not associated with increased cardiovascular morbidity or mortality.⁵ Whether some sulfonylureas (glipizide or glimepiride) or the other antidiabetic agents (especially the insulin sensitizers) are more beneficial for the cardiovascular consequences of T2DM remains to be determined.

Effects on Lipids

Unlike the insulin sensitizers, sulfonylurea treatment probably does not possess lipid-lowering effects other than that due to improved glycemic control. In one study, Panahloo and coworkers⁶¹ examined the effects of sulfonylurea and insulin treatment on glycemia, insulin sensitivity, and lipid concentrations in 20 poorly controlled, diet-treated T2DM subjects who were given sulfonylurea or insulin each for a period of 16 weeks in a randomized crossover study, with a 4-week washout period between each treatment. Subjects were studied at the baselines (B1 and B2) and after each treatment. Expectedly, although treatment with both sulfonylureas or insulin resulted in equal improvement in insulin sensitivity (measured by the metabolic clearance of glucose) and glycemia (HbA_{1c} declined from $11.7 \pm 2.1\%$ to $8.5 \pm 0.9\%$ with sulfonylurea treatment and to $8.6 \pm 1.2\%$ on insulin), surprisingly, there were no differences in lipid concentrations either with improved glycemia or between therapies. However, the potentially atherogenesis-promoting intact proinsulin levels and plasminogen activator inhibitor-1 (PAI-1) antigen activity were higher on sulfonylurea treatment.⁶¹

Prevention of Type 2 Diabetes

A limited number of studies have attempted to determine whether the use of sulfonylurea agents in high-risk subjects can prevent or delay the onset of T2DM. Most of these were of short duration and were generally statistically underpowered. The English Bedford Study did not demonstrate a benefit of tolbutamide 500 mg bid to prevent progression to diabetes.⁶² However, the study by Sartor and colleagues⁶³ did show that tolbutamide 500 mg tid decreased the development of diabetes over 10 years compared with placebo. This study was undermined by a failure to follow an intention-to-treat analysis. In a recent English study, Holman and colleagues⁶⁴ randomized 227 self-referred subjects at increased risk of developing diabetes (FPG between 99 and 139 mg/dL on

two consecutive occasions 2 weeks apart) to either sulfonylurea therapy (gliclazide ≤ 160 mg daily) or a control group allocated either to double-blind placebo or to no tablets. Subjects were also randomly allocated to reinforced or basic healthy-living advice in a factorial design. A total of 201 subjects were evaluated after 1 year in three English and two French centers. Sulfonylurea treatment resulted in a significant reduction in median FPG (by 7 mg/dL) and HbA_{1c} (by 0.2%) compared with the control group. There was no change in insulin sensitivity and β -cell function between groups. Side effects in the sulfonylurea group included weight gain and hypoglycemia. The study is being extended to determine whether sulfonylurea therapy prevents progression to T2DM. It should be mentioned here that the National Institutes of Health (NIH) is presently conducting the 6-year Diabetes Prevention Program in which subjects with impaired glucose tolerance who are at increased risk of developing T2DM are being studied to determine whether intensive lifestyle measures or metformin can prevent or delay the onset of T2DM. There is no sulfonylurea arm in this study. The study completed randomization of 3000 subjects,^{65a} and results were published in 2002.⁶⁵ They demonstrated a 58% reduction in diabetes incidence with lifestyle intervention and 31% reduction with metformin treatment after 3 years followup.

Dosing

The initial starting dose of the sulfonylurea agent depends on the prevailing level of hyperglycemia (Table 32-2). If the initial FPG is <200 mg/dL, sulfonylureas should be started at the lowest dose and titrated upward at weekly intervals so as to achieve an FPG of ≤ 120 mg/dL. If the initial FPG >200 mg/dL, higher initial doses of sulfonylureas may be used. If a patient presents with marked symptoms and hyperglycemia, the sulfonylurea agent may be started at the highest dose and the patient closely followed up.⁶⁶ Studies have shown that the sulfonylureas are better absorbed and are more effective if given about 30 minutes before a meal.¹⁴ This may, however, create a compliance problem for the patients, since it is difficult to remember to take a pill 30 minutes before eating. The goal should be an FPG of ≤ 120 mg/dL and an HbA_{1c} of $<7\%$. All patients should monitor their blood glucose on a regular basis (self-monitored blood glucose [SMBG]), and dosage adjustments in small increments should be made every week depending on SMBG. For once-daily agents, the dose should be given with breakfast or the main meal of the day. Glipizide is best administered 30 minutes before a meal to ensure maximum reduction in postprandial hyperglycemia. However, the sustained-release dosage form should be given with breakfast. In elderly adults over 65 years, patients with hepatic disease, or other patients who may be more sensitive to hypoglycemic drugs, the lowest initial dose should be used and dose adjustments should be made more conservatively.

Special care needs to be taken when transferring a patient from chlorpropamide to any other sulfonylurea therapy. Since chlorpropamide's effects can persist for 1–2 weeks following the discontinuation of therapy, hypoglycemia can result from additive effects of the two agents. The normal starting dose of a sulfonylurea may be used when transferring patients from sulfonylureas (other than chlorpropamide). Patients should be retitrated on micronized glyburide when transferring from conventional glyburide or other oral hypoglycemic agents.

Some patients with T2DM being treated with insulin can be switched successfully to oral sulfonylurea therapy. For patients being treated with <20 U of insulin per day, a lower starting dose

of the sulfonylurea once daily may be tried. For patients being treated with 20–40 U of insulin per day, a higher starting dose (half-maximal) may be tried. For patients being treated with >40 U of insulin per day, it is recommended that the daily insulin dose be decreased 50% and the sulfonylurea be initiated at half-maximal dose.

Side Effects

Sulfonylurea antidiabetic agents are generally well tolerated and have a low incidence of side effects. Hypoglycemia is the most common side effect during sulfonylurea therapy and manifests as hunger, pallor, nausea/vomiting, fatigue, diaphoresis, headache, palpitations, numbness of the mouth, tingling in the fingers, tremors, muscle weakness, blurred vision, hypothermia, uncontrolled yawning, irritability, mental confusion, sinus tachycardia, shallow breathing, or loss of consciousness. Hypoglycemia can be a result of excessive dosage, but it also could be due to other factors such as improper diet or excessive physical activity. Sulfonylurea-induced hypoglycemia can be severe and requires immediate reevaluation and adjustment of both dosage and the patient's diet. The risk of hypoglycemia is also increased in the elderly and when there is poor nutrition, alcohol intake, gastrointestinal disease, or impaired renal function.

Other adverse sulfonylurea effects occur infrequently, typically during the first 6 weeks of therapy. Mild GI effects are common, whereas skin reactions and hematologic complications are rare.^{10,67} Patients often experience some weight gain with use of sulfonylureas. Withdrawal of sulfonylurea therapy due to adverse reactions occurs in <2% of patients. Minor adverse reactions include nausea/vomiting, heartburn, dyspepsia, diarrhea, headache, abdominal pain or cramps, constipation, and paresthesias. These symptoms may subside following a reduction in dosage. Administering the total daily dose in two equally divided doses may also alleviate some of the adverse GI effects. However, severe adverse GI effects may necessitate discontinuance of the drug.

Allergic skin reactions to sulfonylurea include maculopapular rash, urticaria, erythema, and pruritus. These reactions are usually mild, but if they persist or become severe, the drug should be discontinued. Rarely, skin eruptions have progressed to erythema multiforme and exfoliative dermatitis; porphyria cutanea tarda and photosensitivity reactions have been reported. Cholestatic jaundice has also been reported with sulfonylurea therapy, and (rarely) hepatic porphyria has been precipitated by sulfonylureas. The drug should be discontinued if this occurs. Sulfonylureas can cause leukopenia, thrombocytopenia, pancytopenia, agranulocytosis, aplastic anemia, and/or hemolysis, which can lead to hemolytic anemia. These effects are usually mild and typically subside following discontinuance of the drug.

The syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has occurred in patients receiving chlorpropamide. Chlorpropamide occasionally can also cause hyponatremia and water intoxication, which is indistinguishable from SIADH. Although rare, hyponatremia and SIADH have also occurred in patients receiving other sulfonylureas. Most of these affected patients had other variables, which may have been responsible or contributory.

Contraindications

Sulfonylurea use is contraindicated in pregnancy since there are no adequate human studies of effects on the fetus, although animal reproduction studies have shown some adverse fetal effects. If

they are used at all, the decision to administer sulfonylurea drugs must weigh the potential risks to the fetus against the potential benefits to the mother. Because abnormal glucose concentrations are themselves a risk factor for congenital abnormalities, insulin is recommended to maintain blood glucose as close to normal as possible. However, in a recent study, Langer and coworkers⁶⁸ randomized 404 women with gestational diabetes (between 11 and 33 weeks of pregnancy) who were unable to achieve adequate metabolic control with diet and exercise alone to either glyburide or insulin therapy. Adequate control was obtained with significantly less hypoglycemia in the glyburide group than in the insulin group. (Only 4% of glyburide women had to go on insulin.) More importantly, there was no evidence of any of the complications feared to result from fetal or neonatal hyperinsulinemia due to transplacental passage of the sulfonylurea drug. There were no differences between the groups in cord serum insulin concentrations or in the incidence of macrosomia, cesarean delivery, or neonatal hypoglycemia. Glyburide was not detected in the cord serum of any infant, despite measurable serum concentrations in some of their mothers. However, this study does not permit us to draw firm conclusions about the teratogenicity of oral hypoglycemic drugs in early pregnancy (when organogenesis occurs) and thus whether women with T2DM who become pregnant can safely continue oral sulfonylurea agents. Also, since it is not known whether sulfonylureas are excreted in breast milk, it is recommended that sulfonylureas not be used in women who are breastfeeding, to avoid hypoglycemia in nursing infants.

All sulfonylureas are contraindicated in patients with a known sulfonylurea hypersensitivity. Allergic reactions such as angioedema, arthralgia, myalgia, and vasculitis have been reported. Sulfonylureas are also contraindicated in all patients with T1DM and those in acute stress conditions like major surgery, acute myocardial infarction, or trauma.

Renal impairment or hepatic disease can cause elevations in sulfonylurea blood concentrations, and hepatic disease can also reduce gluconeogenic capacity⁶⁹; both problems increase the risk of hypoglycemia, and sulfonylureas should be administered carefully in these patients. Some sulfonylureas like chlorpropamide and acetohexamide can exacerbate hepatic porphyria and should be used cautiously in patients with a history of this condition.

Elderly patients may be more susceptible to the hypoglycemic effects of sulfonylureas. Chlorpropamide can cause prolonged and serious hypoglycemia in the elderly, as well as SIADH. Therefore, this medication is not recommended for use in the geriatric population. The use of sulfonylureas has not been studied systematically in children with T2DM.

Drug Interactions

Although drug interactions for the second-generation sulfonylureas (glyburide and glipizide) are theoretically less of a concern than for the first-generation agents, interactions due to displacement have been reported, and caution should be used if any of the following drugs are prescribed to patients receiving oral sulfonylureas due to the potential for protein-binding interactions and hypoglycemia: clofibrate, salicylates, NSAIDs, and sulfonamides. Also, the interaction between oral anticoagulants and oral sulfonylureas is complex, and it is wise for clinicians to monitor coagulation parameters closely when sulfonylureas and warfarin are used together.⁷⁰

Beta blockers promote hyperglycemia by inhibiting insulin secretion and decreasing tissue sensitivity to insulin. Selective beta

blockers may cause fewer problems with blood glucose regulation, although all beta blockers can still mask the tachycardic response to hypoglycemia. Monoamine oxidase inhibitors (MAOIs) interfere with the compensatory adrenergic response to hypoglycemia and cause clinically significant hypoglycemia in patients receiving oral antidiabetic agents such as glyburide.

Patients on weight loss medication (sibutramine or orlistat) or weight loss diets should be followed closely and often require a reduction in dose or discontinuation of antidiabetic drug therapy coincident with weight loss.⁷¹

Chlorpropamide has been associated with a disulfiram-like reaction after ingestion of ethanol.⁹ Patients who take other oral hypoglycemics and consume ethanol should be counseled on this reaction. In addition, ethanol is known to inhibit gluconeogenesis, and it is possible that hypoglycemia may occur more readily after ethanol ingestion in patients receiving oral hypoglycemics. Miconazole has been reported to inhibit the metabolism of oral antidiabetic agents. Patients should be monitored for hypoglycemia if miconazole is added. It is not clear whether other azole antifungals interact in the same manner.

Repaglinide

Repaglinide is a carbamoylmethyl benzoic acid (CMBA) derivative that belongs to a new class of antidiabetic agents, structurally related to meglitinides (previously known as the nonsulfonylurea moiety of glibenclamide) (Fig. 32-3). Like the sulfonylureas, repaglinide is an insulin secretagogue, and its mechanism of action involves ATP-sensitive K^+ channels.⁷² Repaglinide is unique in that it has a rapid onset and short duration of action; when taken just prior to meals, it replicates physiologic insulin profiles. It has been shown to lower HbA_{1c} levels by 1.6–1.9%. Repaglinide is available as Prandin™ in the United States, Actulin® in Canada, and NovoNorm® in Europe. Prandin was approved by the FDA in December 1997.

Mechanism of Action

Repaglinide binds a characterizable site on the β -cells in the pancreas and closes ATP-dependent potassium channels. The intracellular uptake of repaglinide is very limited; however, intracellular uptake is not required to stimulate insulin secretion.⁷³ Repaglinide's activity is both dose-dependent and glucose-dependent. From *in vitro* studies utilizing mouse islet cells, it has been observed that

repaglinide was more potent at stimulating insulin secretion than the oral sulfonylurea glyburide in the presence of moderate concentrations of glucose; however, in the absence of glucose, glyburide, but not repaglinide, stimulated insulin secretion. Although repaglinide and glyburide are equally potent as potassium channel blockers, the activity of repaglinide on the potassium channel diminishes as glucose concentrations rise from moderate to high.⁷³ In addition, repaglinide does not mimic a second action of glyburide on calcium-dependent insulin exocytosis. This secondary action of glyburide may explain why glyburide is more potent than repaglinide at high glucose concentrations. Repaglinide is not effective in the absence of functioning β cells, as occurs in T1DM.

Pharmacokinetics

Repaglinide is administered orally and is rapidly and completely absorbed from the GI tract. The mean absolute bioavailability is 56%, and peak plasma levels are achieved within 1 hour of administration. More than 98% of the drug is protein bound and is metabolized in the liver by the cytochrome P-450 enzyme system 3A4. There are three major metabolites of the parent compound but none of them have glucose-lowering activity. Elimination of repaglinide is also rapid, with a half-life of 1 hour. Approximately 92% of repaglinide and its metabolites is excreted in the feces, and the remaining 8% is eliminated in the urine. Caution should be used in patients with impaired hepatic function, and longer dosing intervals should be used to assess the extent of glucose control accurately.

Clinical Use and Efficacy

In a 24-week U.S. trial, 361 patients with T2DM were randomized to premeal treatment with placebo or repaglinide 1 or 4 mg. At 6 months, repaglinide 1 or 4 mg decreased mean FPG values by 4 and 49 mg/dL and HbA_{1c} by 1.8–1.9%. In the placebo group, FPG increased by 19 mg/dL. There were no events of severe hypoglycemia, and nearly all those with hypoglycemic symptom episodes had blood glucose levels above 45 mg/dL.⁷⁴

In another U.S. study,⁷⁵ repaglinide was shown to provide glycemic control that was at least as effective and potentially safer than that provided by glyburide. In this prospective, 1-year, multicenter, double-blind, randomized, parallel-group study, 576 patients with T2DM of at least 6 months' duration were randomized to receive monotherapy with repaglinide or glyburide. Repaglinide patients received a starting dose of 0.5 mg three times a day preprandially, adjusted as necessary to 1, 2, or 4 mg before breakfast, lunch, and dinner. Glyburide patients received a starting dose of 2.5 mg before breakfast and increased as necessary to 10 mg bid. The glucose-lowering effect of repaglinide was most pronounced in pharmacotherapy-naïve patients, who showed rapid and marked decreases in mean HbA_{1c} levels from baseline (9.4%) to month 3 (7.6%) and month 12 (7.9%). Mean FPG levels also decreased overall in this group, from 222 mg/dL at baseline to 175 mg/dL at month 3 and to 188 mg/dL at month 12. At endpoint, morning C-peptide levels had increased significantly in glyburide-treated patients compared with those treated with repaglinide, but morning fasting insulin levels did not differ significantly between the two groups. Repaglinide efficacy was sustained over 1 year and was not influenced by age or gender. Overall safety and changes in lipid profile and body weight were similar with both agents. However, weight gain data for the subset of pharmacotherapy-naïve patients suggested that patients on repaglinide gained less weight than those given glyburide. Thus, patients in this study using repaglinide

FIGURE 32-3. Structure of repaglinide.

received the same therapeutic benefits as those using glyburide and may have received additional benefits.

In addition to its efficacy when used as monotherapy, repaglinide is also useful as combination therapy. Several studies have documented that combination treatment with repaglinide and metformin provides superior glycemic control compared with monotherapy with either agent alone.^{76,77} In combination with metformin, HbA_{1c} levels are further reduced by ~1.4% and FPG levels by ~40 mg/dL.

Since repaglinide is quickly absorbed and has a short half-life, it may be advantageous in subjects who are prone to delayed or missed meals. Indeed, results from one study⁷⁸ suggest that treatment with repaglinide in well-controlled T2DM patients who miss or delay a meal is superior to treatment with longer-acting sulfonylurea drugs (such as glyburide) with respect to the risk of hypoglycemic episodes (Fig. 32-4). This double-blind randomized study was designed to compare diurnal blood glucose excursions and the effects of accidental dietary noncompliance in T2DM patients who were well controlled on either repaglinide or glyburide treatment. Repaglinide was administered preprandially with each meal, and glyburide was administered in two daily doses before breakfast and dinner, regardless of whether lunch had been omitted. The diurnal blood glucose levels on a day in which three meals were eaten were compared between the two groups, and the minimum blood glucose concentration (BG_{min}) measurements were compared between lunch and dinner on days with three and two meals. Although the results showed no significant differences between the repaglinide and glyburide groups in average blood glucose levels from fasting blood glucose, the influence on the mean BG_{min} of omitting a meal differed significantly between the repaglinide and glyburide groups. In the latter group, BG_{min} decreased from 77 to 61 mg/dL as a result of omitting lunch, whereas in the repaglinide group, BG_{min} was unchanged for the two-meal day (78 mg/dL) and the three-meal day (76 mg/dL). All hypoglycemic events occurred in the glyburide group on the two-meal day, in connection with omitting lunch. No hypoglycemic events were recorded in the repaglinide group.

Extrapankreatic Effects

So far, there have been no studies on the extrapancreatic effects of repaglinide on insulin sensitivity or other parameters.

Dosage

Since repaglinide has a rapid and short-acting pharmacodynamic profile, it is most effective when given before meals. For

treatment-naïve patients or patients whose HbA_{1c} is less than 8%, therapy may be initiated with a dose of 0.5 mg (immediately before a meal or 15 or 30 minutes prior to eating) and, depending on the response (aiming at postprandial glucose < 160 mg/dL), increased to 2 mg before meals up to four times a day. For patients who have taken oral hypoglycemic agents and whose HbA_{1c} is >8%, a higher initial dose of 1 or 2 mg may be used prior to each meal. After each dose adjustment, at least 1 week should elapse to assess effectiveness. The maximum dose of repaglinide is 4 mg taken with every meal up to four times a day (total 16 mg in a 24-hour period). If a sulfonylurea agent is to be replaced by repaglinide, repaglinide should be started the day after the final dose of the other agent is given. Since overlapping effects are possible, close monitoring for hypoglycemia should be maintained for up to 1 week. If monotherapy alone fails to achieve glycemic goals, combination therapy with metformin (approved by the FDA) or with glitazones (not yet approved by the FDA) may be initiated.

Patients with Hepatic Impairment

Repaglinide is metabolized mainly in the liver, and its clearance is significantly reduced in patients with hepatic impairment. Also, hepatic disease can reduce gluconeogenic capacity, and hence repaglinide should be carefully administered in these patients to avoid the risk of hypoglycemia.

Patients with Renal Impairment

Repaglinide is safe and well tolerated in subjects with varying degrees of renal impairment.⁷⁹ Although adjustment of starting doses of repaglinide is not necessary for renal impairment or renal failure, severe impairment may require more care when upward adjustments of dosage are made. Hemodialysis does not significantly affect repaglinide clearance.

Contraindications/Caution

Repaglinide is contraindicated in patients with a known hypersensitivity to the drug and also in patients with T1DM, as it is not effective in the absence of functioning pancreatic β cells.

There are no adequate human studies regarding the effects of this drug on the fetus, and repaglinide is contraindicated in pregnancy, as are all other oral antidiabetic agents. It is not known whether repaglinide is excreted in breast milk. Because of the possibility of hypoglycemia in nursing infants, it is recommended that repaglinide not be used in women who are breastfeeding. Repaglinide has also not been studied in children and should not be used in them. In the elderly, debilitated, or malnourished, who are more susceptible to the hypoglycemic effects of repaglinide, the drug should be administered with caution and at lower initial doses.

Side Effects

Since repaglinide is an insulin secretagogue like the sulfonylureas, hypoglycemia is the most common side effect. During clinical trials, hypoglycemic occurrences due to repaglinide tended to be lower (16%) than those caused by sulfonylureas (20%). Proper patient selection, dosage, and instructions are important to avoid hypoglycemic episodes. Hypoglycemia may manifest as hunger, pallor, nausea/vomiting, fatigue, perspiration, headache, palpitations, numbness of the mouth, tingling in the fingers, tremors, muscle weakness, blurred vision, hypothermia, uncontrolled yawning, irritability, mental confusion, sinus tachycardia, shallow breathing, and loss of consciousness.

FIGURE 32-4. The minimum blood glucose concentrations (BG) measured between lunch and dinner on days with 3 and 2 meals/day among patients in the repaglinide group and the glyburide group. *, $p < 0.05$ compared with glyburide. (Data from Damsbo et al.⁷⁸)

After hypoglycemia, upper respiratory tract infections (16%) and headache (11%) are the two most common adverse reactions for repaglinide in clinical studies. Sinusitis and arthralgia were reported by 6% of the people, whereas GI disturbances such as nausea/vomiting, diarrhea, constipation, and dyspepsia were less common. Back pain and chest pain were experienced by 5% and 3%, respectively.

Drug Interactions

Repaglinide is metabolized in the liver by the cytochrome P-450 enzyme CYP3A4. Drugs that are involved in the induction or suppression of this enzyme system may alter the expected hypoglycemic action of this agent. The metabolism of repaglinide may be inhibited by antifungal agents such as ketoconazole or miconazole, as well as antibacterial agents such as erythromycin. The result of this enzyme inhibition is a greater hypoglycemic effect from repaglinide. On the other hand, hyperglycemia may occur in patients taking repaglinide concomitantly with CYP3A4 inducers like barbiturates, carbamazepine, and rifampin.

Highly protein bound agents may also potentiate the hypoglycemic effects of repaglinide. These include beta blockers, chloramphenicol, MAOIs, NSAIDs, probenecid, salicylates, sulfonamides, and warfarin, which may lower serum glucose levels when used concomitantly with repaglinide. However, drug interaction studies in healthy volunteers demonstrate that repaglinide has no clinically relevant effect on the pharmacokinetic properties of digoxin, theophylline, or warfarin. The coadministration of cimetidine with repaglinide also did not significantly alter the absorption or disposition of repaglinide.

Nateglinide (Starlix®)

Nateglinide (a D-phenylalanine derivative) is a newly approved nonsulfonylurea insulin secretagogue; like repaglinide, it exerts its glucose-lowering effect through binding to the SUR receptor in the pancreatic β cells and closure of the K_{ATP} channels (Fig. 32-5). Like repaglinide, nateglinide's pharmacokinetic features include rapid absorption and elimination. However, its unique faster kinetics may be explained by the relatively low binding affinity of the drug for the SUR receptor.

Effects on Glycemia

In a recent randomized, double-blind study, Horton and colleagues^{79a} evaluated the efficacy and tolerability of nateglinide and metformin (alone and in combination) in patients with T2DM inadequately controlled by diet (HbA_{1c} level between 6.8% and 11.0%). After a 4-week placebo run-in period, subjects received 24

FIGURE 32-5. Structure of nateglinide.

NATEGLINIDE

weeks' treatment with 120 mg nateglinide before meals ($n = 179$) 500 mg metformin three times a day ($n = 178$), combination therapy ($n = 172$), or placebo ($n = 172$). At the end of the study HbA_{1c} was significantly reduced from baseline with nateglinide and metformin but was increased with placebo (-0.5 , -0.8 , and $+0.5\%$, respectively). Combination therapy with nateglinide and metformin was additive with decreases in HbA_{1c} of 1.4% and FPG of 43 mg/dL. In this study, after a Sustacal® challenge, there was a greater reduction in mealtime glucose with nateglinide monotherapy compared with metformin monotherapy or placebo. The authors of this study concluded that nateglinide and metformin monotherapy each improved overall glycemic control, but by different mechanisms. Nateglinide decreased mealtime glucose levels, whereas metformin primarily affected FPG. In combination, nateglinide and metformin had complementary effects, improving HbA_{1c}, FPG, and postprandial hyperglycemia.

Extrapankreatic Effects

In a recent study, Hu and coworkers^{79b} assessed the tissue specificity of nateglinide by examining its effect on K_{ATP} channels in rat tissue. Data from this study indicated that nateglinide has a 300-fold greater selectivity for pancreatic K_{ATP} channels compared with cardiovascular K_{ATP} channels. This property may be of potential benefit, since at concentrations effective in stimulating insulin secretion, nateglinide among the insulin secretagogues is least likely to cause detrimental cardiovascular effects via blockade of cardiovascular K_{ATP} channels.

BIGUANIDES

Phenformin and metformin are oral biguanide agents (Fig. 32-6) that were introduced for the treatment of T2DM in the late 1950s.⁸⁰ Phenformin was withdrawn from clinical use in the late 1970s because of an association with lactic acidosis. The risk for lactic acidosis is considerably lower with metformin. Its use was continued in many other countries until it was approved for use in the United States in 1995 for the treatment of T2DM either as monotherapy or in combination with sulfonylureas, α -glucosidase inhibitors, or insulin. Subsequently, it has also been approved for use in combination with rosiglitazone, pioglitazone, and repaglinide.

FIGURE 32-6. Structure of metformin.

METFORMIN

Mechanism of Action

Although its mechanism of action has not been clearly determined, decreased hepatic gluconeogenesis is thought to be the primary therapeutic effect of metformin in T2DM.⁸⁰ In addition, metformin appears to improve utilization of glucose in skeletal muscle and adipose tissue by increasing cell membrane glucose transport. This effect may be due to improved binding of insulin to insulin receptors since metformin is not effective in diabetics without some residual functioning pancreatic islet cells.⁸⁰ Another effect of metformin that may contribute to its glucose-lowering properties is its ability to decrease fatty acid oxidation.⁸⁰ Other mechanisms may include decreased intestinal glucose absorption; however, this has only been observed in animals.⁸⁰ Thus, in insulin-resistant patients with T2DM, metformin increases insulin sensitivity by both decreasing hepatic glucose output and enhancing peripheral glucose uptake. It has no direct effects on insulin secretion^{80,81} and hence, in contrast to sulfonylureas, which have a hypoglycemic effect, metformin does not generally cause hypoglycemia when given alone. In clinical practice, metformin demonstrates more of an anti-hyperglycemic action than a hypoglycemic action. Unlike phenformin, metformin does not inhibit the mitochondrial oxidation of lactate unless plasma concentrations of metformin become excessive (i.e., in patients with renal failure) and/or hypoxia is present.⁸²

In a recent study, 3 months of metformin treatment reversed the increased activity of lymphocyte plasma cell differentiation antigen (PC-1) found in T2DM.⁸³ PC-1 is an inhibitor of insulin receptor tyrosine kinase activity and has been implicated in the pathogenesis of insulin resistance in T2DM. Data from this study were consistent with a role of PC-1 in insulin resistance and suggest a new mechanism of action for metformin via PC-1 inhibition.⁸³

Pharmacokinetics

The bioavailability of metformin is 50–60%. Food decreases the extent and slightly delays the absorption of metformin; however, it should be taken with meals.⁸⁰ Metformin is distributed rapidly into peripheral body tissues and fluids and appears to distribute slowly into erythrocytes and to a deep tissue compartment (most likely GI tissues). The highest concentrations of metformin are found in the GI tract (10 times the concentrations in the plasma) and lower concentrations in the kidney, liver, and salivary gland tissue. Metformin does not bind to liver or plasma proteins. It is not metabolized by the liver, which may explain why the risk of lactic acidosis is much less for metformin than for phenformin.⁸¹ Metformin is excreted by the kidneys, largely unchanged, through an active tubular process. Approximately 30% of an oral dose is excreted in the feces, presumably as unabsorbed metformin, and about 90% of a dose is excreted by the kidneys within 24 hours. The plasma half-life is approximately 6.2 hours, and the blood half-life is approximately 17.6 hours in patients with normal renal function. Half-life is increased in patients with renal impairment. Metformin is removed with hemodialysis.

Clinical Use and Efficacy

Metformin is approved for use as monotherapy and also in combination with sulfonylureas, repaglinide, α -glucosidase inhibitors, and glitazones. Several controlled clinical studies of metformin

monotherapy have demonstrated significant reductions in both fasting blood glucose levels (60–70 mg/dL) and HbA_{1c} levels (1–2%) compared with placebo in patients poorly controlled by diet alone.^{84–91} The efficacy of metformin in reducing plasma glucose levels in a predominantly overweight population is comparable to that seen with sulfonylureas.^{85,88,89} Because of its potential to ameliorate insulin resistance, prevent weight gain, and improve lipid levels, metformin may be best suited for initial monotherapy in obese patients with more severe insulin resistance and dyslipidemia. In these patients, metformin does not cause weight gain and, in fact, may cause a modest weight loss due to drug-induced anorexia. Metformin also decreases plasma VLDL triglycerides, resulting in modest decreases in plasma triglycerides and total cholesterol. Patients receiving metformin show significant improvement in FPG and HbA_{1c} levels and a tendency toward improvement in the lipid profile, especially when baseline values are abnormally elevated.

When monotherapy alone does not result in acceptable glycemic control, metformin should be combined with a sulfonylurea and/or other oral antidiabetic oral agents. In 423 patients failing sulfonylurea treatment (FPG 249 mg/dL), the addition of metformin decreased the FPG by 63 mg/dL and the HbA_{1c} value by 1.7%.⁸⁶ Nearly 25% of these patients whose disease was poorly controlled achieved an HbA_{1c} value of <7% with the addition of metformin therapy. These results indicate that the hypoglycemic action of metformin is additive to that of the sulfonylureas. In sulfonylurea-treated patients with T2DM who do not achieve optimal control or who experience secondary failure, it is important not to discontinue sulfonylurea therapy, but to add metformin. Discontinuation of sulfonylurea therapy and substitution of metformin will not decrease the FPG below that observed with sulfonylurea monotherapy alone. The sulfonylurea is continued with metformin to maintain its effect on pancreatic insulin secretion.

Although primarily thought of as a drug for the overweight, it should be noted that, as with sulfonylureas, glycemic improvement is also demonstrated in patients who are not obese.^{80,91}

Effects on Insulin Sensitivity

In addition to improving glycemia, metformin has been shown to have insulin-sensitizing effects in humans using the hyperinsulinemic glucose clamp technique. Most studies have documented an increase of ~20–30% in insulin-mediated glucose uptake. This increase in glucose uptake is mainly due to stimulation of nonoxidative glucose disposal (primarily glycogen synthesis).⁹¹ However, as an insulin sensitizer, metformin is less potent than the glitazones in stimulating insulin-mediated glucose uptake into muscle tissue. In a head-to-head comparison, after 3 months of therapy, despite equivalent glucose lowering, the mean rate of glucose disposal increased by 54% during troglitazone therapy and 13% during metformin therapy. Endogenous glucose production, however, decreased during metformin therapy by a mean of 19%, whereas it was unchanged by troglitazone therapy⁹⁰ (Fig. 32-7).

Effects on Insulin Secretion

In clinical studies, metformin does not appear to have a direct effect on β -cell function. In metformin-treated patients with diabetes, both fasting and postprandial insulin levels decrease,^{80,91} secondary to the normal compensatory response of the pancreas to lower prevailing glucose levels and enhanced insulin sensitivity.

FIGURE 32-7. Maximum glucose disposal rate (Rd) obtained during the hyperinsulinemic clamp technique, before and after 3 months of therapy with metformin and troglitazone. *, $p = 0.006$; **, $p = 0.03$. (Data from Inzucchi et al.⁹⁰)

Also, studies to date with the hyperglycemic clamp technique have failed to demonstrate any effect of metformin on either total insulin secretion or first- or second-phase insulin secretion in patients with T2DM. Some studies during an oral glucose tolerance test (OGTT) have demonstrated an increase in insulin secretion after metformin treatment.⁹¹ However, these increases in insulin secretion have been small and probably secondary to amelioration of glucose toxicity.

A recent report notes a direct effect of metformin on pancreatic β cells. Patane and colleagues⁹² demonstrated that in rat pancreatic islets whose secretory function has been impaired by chronic exposure to elevated free fatty acids (FFAs) or glucose levels, metformin was able to restore the intracellular abnormalities of glucose and FFA metabolism and to restore a normal secretory pattern. These data raise the possibility that, in diabetic patients, metformin (in addition to its peripheral effects) may have a direct beneficial effect on β -cell secretory function.⁹² Interestingly, metformin treatment has also been shown to lower concentrations of intact and des 31,32 proinsulin in T2DM.⁹³ These molecules have been postulated to play a role in the development of atherosclerosis, and the long-term effect of metformin treatment on proinsulin-like molecules and atherogenesis needs to be assessed further.

Effects on Weight

Unlike the insulin secretagogues and the thiazolidinediones, metformin therapy does not result in weight gain in patients with T2DM who receive metformin alone or in combination with other oral agents or insulin.^{81,89,90,94,95} Most studies show modest weight loss (2–3 kg) during the first 6 months of treatment.⁸¹ Metformin therapy is also associated with weight loss in nondiabetic subjects.⁹⁶ The exact mechanisms by which metformin prevents weight gain or induces weight loss have not been determined. Several mechanisms have been postulated by which metformin might prevent weight gain or induce weight loss. These include a decrease in food consumption, increase in energy expenditure, and reduction of hyperinsulinemia.⁹¹ Some animal studies suggest an anorectic effect, but in human studies, it has not been possible to differentiate between a central effect of metformin in decreasing calorie intake versus an increase in energy expenditure.⁹¹ Incidentally, in nondiabetic and polycystic ovary syndrome (PCOS) subjects, metformin therapy is associated with a reduction in leptin levels and restoration of menses.^{97–99}

Effects on Lipids

In addition to its glycemic effects, metformin is known to have favorable effects on plasma lipids, in both diabetic and nondiabetic subjects.⁹¹ As monotherapy, metformin decreases plasma triglyceride and LDL cholesterol levels by 10–15%^{100,101} and also reduces postprandial hyperlipemia, plasma FFA levels, and FFA oxidation. The decrease in plasma triglyceride concentration is independent of changes in the plasma glucose level since metformin reduces triglyceride levels in nondiabetic patients with hypertriglyceridemia.^{100,101} Metformin therapy does not appear to affect HDL cholesterol levels consistently, which either do not change or increase slightly after metformin therapy.⁹¹

Effects on Blood Pressure

In some clinical studies, metformin treatment has been associated with a modest drop in blood pressure in patients with T2DM. However, most studies have failed to demonstrate any decrease in systemic blood pressure with metformin treatment.⁹¹

Effects on Other Cardiovascular Risk Factors

Insulin resistance is known to be associated with a hypercoagulable state¹⁰² and an increase in many cardiovascular risk factors, including PAI-1. Metformin has many beneficial effects on cardiovascular risk factors.^{84,103,104} Elevated PAI-1 levels are decreased with metformin therapy in patients with and without diabetes.⁹¹ In the French Biguanides and the Prevention of the Risk of Obesity (BIGPRO) I trial, metformin therapy also reduced tissue-type plasminogen activator (tPA) antigen and von Willebrand factor (vWF) levels. These two factors are mainly secreted by endothelial cells and metformin therapy appeared to have suppressive effects on the production or metabolism of these two hemostatic proteins.¹⁰⁵ In another 18-month study, metformin treatment in elderly T2DM patients was associated with significant reductions in markers of platelet function, thrombin generation, and fibrinolysis inhibition (PAI-1 activity, PAI-1 antigen).¹⁰⁶ However, in this study, increases in some fibrinolytic activation markers (tPA and antithrombin (AT)-III; $p < 0.01$) were also observed.

Effects on Cardiovascular Disease

The long-term effects of metformin on serum lipids and other metabolic risk factors appear to have cardiovascular benefits. In the UKPDS, metformin therapy in obese, newly diagnosed patients with T2DM was associated with a significant decrease in cardiovascular and all-cause mortality.¹⁰⁷ Whether this benefit with metformin treatment was due to the absence of weight gain or other beneficial effects on the metabolic syndrome of diabetes remains to be determined. It must also be remembered that in the UKPDS, when metformin treatment was added in patients who had failed sulfonylurea therapy, there was a significant and paradoxical increase in cardiovascular and all-cause mortality (Fig. 32-8). This question was addressed in a subsequent analysis by Turner and colleagues,^{107a} who found that all the relative increase in mortality observed in the patients who received sulfonylurea plus metformin compared with those who received sulfonylurea alone resulted from a significant reduction in the expected number of deaths in the latter group; there was no increase in mortality in the sulfonylurea plus metformin group. In absolute terms, the number of fatal heart

FIGURE 32-8. Risk reduction with metformin monotherapy and in combination with sulfonylureas in the UKPDS. MI, myocardial infarction. (Data from Turner et al.^{107a})

attacks actually decreased in the sulfonylurea plus metformin group compared with the expected number of deaths.^{107a} The investigators also performed a meta-analysis of all patients receiving sulfonylurea plus metformin in the UKPDS and reported significant reductions in all diabetes-related endpoints and for myocardial infarction.

Effects on PCOS

Women with PCOS are characterized by chronic anovulation and infertility due to excessive androgen production. There is evidence to suggest that this hyperandrogenism may be secondary to insulin resistance and chronic hyperinsulinemia.¹⁰⁸ Several, but not all, studies have shown that in patients with PCOS, metformin improves glucose tolerance and insulin sensitivity and also normalizes plasma sex hormone binding and free testosterone levels.^{109,110} In a recent study in 43 amenorrheic women with PCOS, metformin treatment for 6 months was found to reduce the endocrinopathy of PCOS and allow resumption of normal menses in most (91%) previously amenorrheic women with PCOS.⁹⁹

Effects on Prevention of Type 2 Diabetes

Most patients with T2DM have impaired glucose tolerance (IGT) for several years before progressing to diabetes. Persons with IGT tend to have both insulin resistance and β -cell dysfunction; their FPG values during a 75-g OGTT are ≤ 140 mg/dL, and their 2-hour postglucose values are between 140 and 199 mg/dL.¹¹¹ Metformin is known to improve insulin sensitivity, lower plasma insulin levels and blood pressure, and improve lipid profiles in nondiabetic insulin-resistant individuals.^{91,112} Hence, metformin therapy is one of the arms of the Diabetes Prevention Program, which is a large randomized placebo-clinical trial being conducted by the NIH to determine whether it is possible to prevent or delay the development of T2DM in high-risk individuals with IGT using intensive lifestyle measures or pharmacologic treatment. The study recruitment of 3000 subjects⁶⁵ was completed in 2002^{65a} with a 31% reduction in the incidence of T2DM after 3 years of treatment with metformin.

Dosing

Metformin should be taken with meals, and the starting dose (500 or 850 mg with breakfast or 500 mg with breakfast and dinner) and

be increased slowly at weekly or biweekly intervals to minimize GI side effects.⁸⁰ Metformin lowers fasting plasma glucose and HbA_{1c} in a dose-related manner, and although benefits are observed at lower doses, significant glycemic responses to metformin are usually seen at doses of approximately 1500 mg/day or greater. Data from one study suggest that most patients will achieve maximal efficacy at a daily dosage of 2000 mg (1000 mg bid), although some patients may achieve additional benefit if the dosage is increased to 2500 mg.⁸⁷ The maximum daily dose of metformin is 2550 mg. Doses above 2000 mg daily may be better tolerated when given 3 times a day with meals. The glycemic goal should be an FPG ≤ 120 mg/dL and HbA_{1c} $< 7\%$. If adequate glycemic control is not achieved with maximum doses of metformin (HbA_{1c} $> 8\%$), combination therapy should be considered.

Side Effects

Adverse GI effects are seen in approximately 30% of patients taking metformin. These include anorexia, nausea/vomiting, abdominal discomfort, dyspepsia, flatulence, diarrhea, and metallic taste. These side effects tend to decline with continued use and can be minimized by initiating therapy with low doses of metformin. The risk of hypoglycemia is much less common with metformin than with the sulfonylureas.⁸⁰ However, hypoglycemia has been reported with metformin.⁸⁰ Since metformin reverses insulin resistance, and subsequently causes a decrease in insulin concentrations, metformin-induced hypoglycemia is usually mild and does not necessitate the discontinuation of therapy. Hypoglycemia is more common when metformin is coadministered with other oral hypoglycemic agents or when there is deficient caloric intake or strenuous exercise not compensated by caloric supplementation. Asymptomatic vitamin B₁₂ deficiency was reported with metformin monotherapy in 9% of patients during clinical trials. Serum folic acid concentrations did not decrease significantly. Five cases of megaloblastic anemia have been reported with metformin (none in the United States). Annual screening for hematologic changes is recommended during therapy with metformin. Weight loss may occur during therapy with metformin, perhaps as a result of its ability to cause anorexia. In contrast, sulfonylureas and insulin tend to cause weight gain. Up to 5% of patients cannot tolerate metformin and require discontinuation of this medication.

Contraindications/Caution

Since metformin is largely eliminated unchanged in the urine via glomerular filtration and tubular secretion, it is contraindicated in patients with renal disease or renal impairment (serum creatinine > 1.5 mg/dL in men and > 1.4 mg/dL in women). In patients with reduced muscle mass, such as elderly patients (especially those older than 80 years of age), the serum creatinine concentration may underestimate the glomerular filtration rate, and creatinine clearance should be determined. If the creatinine clearance is < 70 mL/min, metformin should not be given.⁹³ Renal dysfunction also increases the risk of adverse reactions such as lactic acidosis from metformin. Lactic acidosis can also occur in patients predisposed to lactic acidosis such as those with hepatic disease, cardiac disease (e.g., heart failure or acute myocardial infarction), severe infection, severe trauma, dehydration, severe burns, hyperosmolar nonketotic coma, major surgery, or alcoholism. Metformin is contraindicated in these patients.⁸⁰

Metformin should also not be used in diabetic patients with congestive heart failure requiring pharmacologic therapy because in this situation, decreased renal perfusion and glomerular filtration rate can impair metformin excretion. Metformin should also be withheld at the time of or prior to the performance of x-ray procedures involving intravenous radiographic contrast agents because of an increased risk of renal impairment and possible lactic acidosis. Metformin should be reinstituted only after renal function has been reevaluated after 48 hours and found to be normal. In addition, caution should be used in patients with blood glucose levels persistently >300 mg/dL, since this level of hyperglycemia can impair kidney function.¹¹³

The safety of metformin in pregnant and lactating women has not been established. In one report of metformin use in pregnancy from South Africa, the neonatal mortality rate was lower in patients receiving metformin than in mildly diabetic controls.¹¹⁴ In another report, slightly higher incidences of polycythemia and necrotizing enterocolitis were noted in the metformin group, and the most frequently encountered problems in the neonate were jaundice, polycythemia, and hypoglycemia.¹¹⁵

Recently, metformin has received approval from the FDA for use in adolescents with T2DM.

Drug Interactions

Cimetidine decreases the renal clearance of metformin secondary to a decrease in metformin renal tubular secretion. However, metformin has little effect on the pharmacokinetics of cimetidine. Other cationic drugs that are excreted via renal tubular transport may also interfere with the clearance of metformin. These drugs include amiloride, digoxin, morphine, procainamide, quinidine, quinine, ranitidine, triamterene, trimethoprim, and vancomycin. Concomitant administration of furosemide increases plasma metformin concentrations without any significant change in metformin renal clearance. On the other hand, metformin decreases furosemide plasma and blood maximum concentrations by 31% and 12%, respectively. Furosemide's terminal half-life was also decreased by 32% without any significant change in renal clearance. Nifedipine, and possibly other calcium channel blockers, increases the absorption of metformin. Although the clinical implications of these interactions are minimal, patients on the above drugs and metformin should be closely monitored.

Metformin can also inhibit the absorption of cyanocobalamin (vitamin B₁₂) by competitively blocking the calcium-dependent binding of the intrinsic factor–vitamin B₁₂ complex to its receptor. Patients should be monitored for possible development of anemia.

α -GLUCOSIDASE INHIBITORS

There are two α -glucosidase inhibitors currently marketed in the United States, acarbose (Precose®) and miglitol (Glyset®) (Fig. 32-9). The first, acarbose, was approved in the United States in 1995 for use as monotherapy or in combination with insulin, metformin, or sulfonylureas. Miglitol was approved by the FDA in December 1996 but was not marketed until mid-1999. Miglitol is only approved for use as monotherapy and in combination with sulfonylureas. At recommended doses, both agents have only modest effects on HbA_{1c} levels (mean 0.5–1.0% reductions). α -Glucosidase inhibitors are suitable alternatives in patients with mild to moderate hyperglycemia (especially postprandial hyperglycemia) and, be-

FIGURE 32-9. Structure of miglitol.

cause of their relative safety, are often useful as monotherapy in the elderly T2DM patient. In addition, although not FDA-approved for T1DM, acarbose has been utilized as an adjunct to insulin therapy to reduce postprandial plasma glucose levels in these patients.

Mechanism of Action

Acarbose and miglitol are potent inhibitors of the α -glucosidase enzymes present in the brush border of the enterocytes located in the proximal portion of the small intestine.^{116,117} Although the mechanisms of action for the α -glucosidase inhibitors are similar, they are not identical. Both agents significantly inhibit glycoamylase, followed by sucrase, maltase, and dextranase. However, miglitol is a more potent inhibitor of sucrase and maltase than acarbose. Both drugs also inhibit isomaltase but, in contrast to acarbose, miglitol does not inhibit pancreatic α -amylase. The inhibition of sucrase (which prevents the conversion of sucrose to fructose and glucose), glycoamylase, maltase, and isomaltase results in delayed carbohydrate digestion and absorption throughout the small intestine. Clinically, this leads to delayed intraluminal production of monosaccharides (i.e., glucose), delayed and prolonged postprandial rises in plasma glucose, and a blunted plasma insulin response. In addition to the above actions, miglitol (but not acarbose) interacts weakly with the intestinal sodium-dependent glucose transporter, but this does not appear to affect the physiological absorption of glucose clinically. Miglitol (unlike acarbose) also minimally inhibits the lactase enzyme, but this does not produce clinical lactose intolerance. When used as monotherapy, both agents do not enhance insulin secretion and in overdose will not result in hypoglycemia.

Pharmacokinetics

The two agents differ significantly in their rate of systemic absorption. Systemic absorption of active acarbose is only about 2% whereas after oral administration of a 25-mg dose of miglitol, there is rapid and nearly complete systemic absorption of the drug. Local systemic absorption of acarbose is therapeutically desirable, since the drug acts locally in the GI tract. Acarbose is metabolized within the GI tract, and metabolism occurs principally by intestinal microbial flora, intestinal hydrolysis, and the activity of digestive enzymes. At least 13 metabolites have been identified, with approximately 34% of the major metabolite fractions being absorbed systemically and appearing in the urine as sulfate, methyl, and glucuronide conjugates. One metabolite has α -glucosidase-inhibitory effects. This active metabolite, along with the parent compound, is recovered in the urine and accounts for about 2% of the total

administered dose. Plasma elimination half-life of acarbose is about 2 hours in healthy adults, and most of an oral dose (~51%) is excreted through the feces.

Unlike acarbose, miglitol is systemically absorbed via a jejunal transport mechanism similar to that of glucose absorption. Oral absorption of miglitol is saturable at high doses; only 50–70% of a 100-mg dose is systemically absorbed. There is no evidence at this time that systemic absorption is required for miglitol activity, but it appears that miglitol concentrates in intestinal enterocytes to exhibit its action locally in the GI tract.¹¹⁷ The drug distributes primarily into extracellular fluid and is minimally protein-bound. Unlike acarbose, miglitol is not metabolized in any way and is excreted unchanged by the kidneys. More than 95% of a 25-mg dose is recovered in the urine within 24 hours; at higher doses, the cumulative percentage recovered is somewhat less due to lower bioavailability of the higher doses. The plasma elimination half-life of miglitol is about 2 hours in healthy adults. In patients with severe renal impairment (i.e., CrCl < 25 mL/min), both acarbose and miglitol attain systemic peak and AUC concentrations that are roughly 5–6 times and 2 times higher, respectively, than in patients with normal renal function. Thus patients with renal failure are expected to accumulate both drugs to some degree. The pharmacokinetics of acarbose have not been studied in patients with cirrhosis. Because miglitol is not metabolized by the liver, the pharmacokinetics in patients with cirrhosis are not altered. For both drugs, no significant differences in pharmacokinetics have been observed based on age, race, or gender.

Clinical Use and Efficacy

Acarbose is approved for use as monotherapy or in combination with insulin, metformin, or sulfonylureas.^{116,117} Miglitol is only approved for use as monotherapy and in combination with sulfonylureas. To be maximally effective, both drugs must be administered at the start of a main meal. This is because they are competitive inhibitors and must be present at the site of enzymatic action at the same time the carbohydrates are present in the small intestine. The affinity of the α -glucosidase inhibitors for the α -glucosidase receptors is much greater than that of the oligo- or disaccharides in foods. Taking the medication before or more than 15 minutes after the start of the meal reduces the impact of the medication on postprandial blood glucose. Also, to be clinically effective, the patient must be consuming a diet high in complex carbohydrates (roughly $\geq 50\%$ of calories)¹¹⁷ since the glycemic response to acarbose and miglitol is dependent on the carbohydrate content of the diet. Several randomized, double-blind, placebo-controlled trials have demonstrated that the addition of acarbose or miglitol to diet therapy significantly reduces postprandial glucose and HbA_{1c} levels compared with placebo.^{116–122} Monotherapy with these agents lowers mean postprandial glucose levels by ~40–60 mg/dL and mean fasting glucose levels by 10–20 mg/dL; overall, mean HbA_{1c} levels are reduced 0.5–1.0%^{116–122} Fig. 32–10.

In combination therapy with sulfonylureas, metformin, and insulin, acarbose further reduces mean HbA_{1c} between 0.3 and 0.5% and mean postprandial glucose between 25 and 30 mg/dL from baseline.^{123–125} Miglitol in combination therapy with sulfonylureas reduces mean HbA_{1c} by 0.7% and mean 1-hour postprandial glucose by ~60–70 mg/dL. Compared with sulfonylureas or metformin, acarbose and miglitol possess less potent effects on fasting glucose and are typically reserved for use as monotherapy in patients with mild-to-moderate hyperglycemia, particularly postpran-

FIGURE 32-10. Mean changes in fasting glucose (FPG), post-prandial glucose (PPG) and HbA_{1c} in acarbose- and miglitol-treated patients. (Data from refs. 116–122.)

dial hyperglycemia. In addition, the absence of hypoglycemia with these agents when used as monotherapy makes them particularly useful and relatively safe in elderly T2DM patients.¹²⁶

Effects in Type 1 Diabetes

Although α -glucosidase inhibitors are not FDA-approved for use in T1DM, acarbose has been utilized in these patients as an adjunct to insulin therapy to reduce postprandial plasma glucose levels.^{127,128} Riccardi and colleagues¹²⁷ evaluated the efficacy and safety of acarbose in the treatment of T1DM in a placebo-controlled, double-blind, multicenter Italian study. After a 6-week run-in, 121 patients with T1DM were randomized to acarbose or placebo and to a high- or low-fiber diet for 24 weeks. The acarbose dose was 50 mg tid for the first 2 weeks and 100 mg tid for the subsequent weeks. At the end of 24 weeks of treatment, an intention-to-treat analysis showed that acarbose decreased 2-hour postprandial plasma glucose levels (220 ± 15 mg/dL versus 268 ± 15 mg/dL; $F = 6.1$, $p < 0.02$) compared with placebo. There was no significant effect of acarbose on HbA_{1c} or the number of hypoglycemic episodes. Interestingly, in this study, the effect of acarbose on blood glucose control was not influenced by the amount of carbohydrate and/or fiber intake. As expected, the incidences of adverse GI events were 75% and 39% in acarbose and placebo groups, respectively. The authors concluded that acarbose in combination with insulin reduces postprandial plasma glucose levels in T2DM patients who are not satisfactorily controlled with insulin alone.

In another double-blind, placebo-controlled, crossover study, Koch and associates¹²⁸ investigated in a German study whether acarbose therapy enables patients with T1DM to administer insulin injections at the same time as meals without adverse glycemic consequences, thus negating the need for an injection-meal interval (IMI). Results from this study provided strong evidence that acarbose prevents the marked increase in postprandial glucose level normally observed when regular insulin is administered with, rather than before, a meal. Acarbose may thus be useful for patients with T1DM who find IMIs inconvenient.

Effects on Insulin Sensitivity

Although studies in animal models suggest that long-term treatment with an α -glucosidase inhibitor (miglitol) improves insulin sensitivity and may have vascular protective effects in obese insulin-resistant rats,¹²⁹ studies in human insulin-resistant T2DM subjects using the insulin/glucose clamp method have yielded conflicting results. One study showed that miglitol-induced improve-

ment in postprandial hyperglycemia was not associated with improved insulin sensitivity,¹³⁰ whereas in a recent study, acarbose at up to 300 mg daily for 12 months was associated with significant improvements in insulin sensitivity as measured by the hyperglycemic clamp technique and by homeostasis model assessment (HOMA) along with reduced glycemia.^{130a}

Effects in Reactive Hypoglycemia and the Dumping Syndrome

α -Glucosidase inhibitors appear to have beneficial effects in people with reactive hypoglycemia and those with the dumping syndrome. In one study¹³¹ of 21 nonobese patients (6 males, 15 females) with reactive hypoglycemia, acarbose treatment for 3 months blunted post-OGTT increases in insulin and C-peptide levels and reduced the frequency of hypoglycemic attacks from four times a week to one. Similar beneficial effects were reported in another study.¹³²

Cardiac Effects

In rabbits,¹³³ miglitol appears to have a dose-dependent effect on reducing myocardial infarct size. Inhibition of glycogenolysis and lactate formation has been suggested to be the responsible mechanism. As yet, there are no human studies in this field.

Effects on Weight

Due to polysaccharide metabolism by colonic microflora and the capacity of the large bowel to conserve calories, there is minimal calorie loss associated with acarbose and miglitol therapy. Hence, in clinical practice, dramatic weight loss is not commonly associated with acarbose or miglitol therapy (in contrast to animal studies).¹¹⁷ Weight loss, if it occurs, is typically mild (i.e., 0.8–1.4 kg over 1 year in clinical studies). In humans, acarbose and miglitol also appear to offset the insulinotropic effects and weight gain associated with sulfonylurea treatment when they are added to combination therapy.¹¹⁷ The exact metabolic or pharmacologic mechanism(s) responsible for α -glucosidase-induced weight loss remains unknown.

Effects on Lipids

In some studies, α -glucosidase inhibitors are associated with decreases in triglyceride levels.^{117, 134, 135} In a study from Japan¹³⁴ of 20 patients with T2DM, acarbose not only inhibited the postprandial increase of both plasma glucose and insulin but also significantly suppressed the postprandial increase of serum triglycerides and serum remnant-like cholesterol particles. In addition, acarbose inhibited the postprandial decline of apolipoprotein C-II, and decreased postprandial serum apolipoprotein C-III levels. There is also evidence that acarbose may reduce triglyceride levels in nondiabetics, and the drug may be a useful adjunct to dietary therapy in nondiabetic patients affected by severe hypertriglyceridemia.¹³⁵

Prevention of Type 2 Diabetes

Currently, an international study (the STOP-NIDDM Trial) is evaluating the efficacy of an α -glucosidase inhibitor to prevent or delay the development of T2DM in a population with impaired glucose tolerance (IGT) who are at increased risk of developing T2DM.¹³⁶ A total of 1418 subjects diagnosed with IGT according to the

World Health Organization's criteria with an FPG of ≥ 100 mg/dL will be randomized in a double-blind fashion to receive either acarbose (100 mg tid) or placebo for a median follow-up period of 5 years. The primary endpoint is the development of T2DM diagnosed using a 75-g OGTT according to the current diagnostic criteria. The secondary endpoints are changes in blood pressure, profile, insulin sensitivity, cardiovascular events, and morphologic profile. The study is ongoing and hopefully may answer the question of whether acarbose can prevent or delay the progression of IGT to T2DM.

Dosage

Acarbose and miglitol are administered with the first bite of main meal. If patients do not have oral dietary intake, they should not take these agents. To minimize GI side effects, both acarbose and miglitol should be started at 25 mg po 3 times per day, with the first bite of each main meal. To reduce GI side effects, some patients may benefit from an initial dose of 25 mg po once daily for 1 week, titrated up as tolerated to 25 mg po 3 times per day. After 4–8 weeks of the 25-mg po three times per day dose, the dosage may be increased if needed to 50 mg po 3 times daily. One-hour postprandial glucose levels throughout treatment and an HbA_{1c} level at 3 months should be used to determine response to therapy. If at 3 months the HbA_{1c} level is not satisfactory, the dose may be titrated to the maximum recommended of 100 mg po three times per day. The usual maintenance range is 50–100 mg po three times per day. One-hour postprandial glucose levels should be used to determine response to therapy to titrate dose. In adults weighing < 60 kg, the maximum recommended dose of acarbose is 50 mg tid. Patients who do not respond to monotherapy should be changed to another form of therapy or considered for oral combination therapy in order to achieve optimal glycemic goals.

Patients with Renal Impairment

There is no experience with either acarbose or miglitol in patients with serum creatinine > 2 mg/dL, and treatment of these patients with acarbose or miglitol is not recommended.

Contraindications

Acarbose and miglitol are contraindicated in patients with inflammatory bowel disease, colonic ulceration, ileus, partial or predilection to GI obstruction, or GI disease involving disorders of sorption or digestion. Both drugs should be used cautiously in patients with hiatal hernia or other conditions that might be exacerbated by increased formation of gas. If a patient has poor oral intake, continual vomiting, or diarrhea, acarbose and miglitol therapy should be withheld until adequate oral dietary intake resumes. Since miglitol elimination is dependent on glomerular filtration, the drug may accumulate in patients with renal impairment. Hence, the drug should not be used in patients with CrCl < 25 mL/min or serum creatinine ≥ 2.0 mg/dL. Acarbose is contraindicated in patients with cirrhosis. If hepatic enzyme elevations occur during acarbose therapy, dose reduction or discontinuation of acarbose may be necessary, particularly if such elevations persist. However, there are two studies whose results document the good tolerability and efficacy of acarbose therapy in patients with chronic liver disease.^{137, 138}

Acarbose and miglitol have not been studied in pregnancy and should not be used in pregnant or lactating women. The safety and effectiveness of acarbose and miglitol in children have not been established.

Side Effects

Hypoglycemia

When used as monotherapy, acarbose and miglitol do not enhance insulin secretion and hence in overdose do not cause hypoglycemia. However, when these agents are used in combination with insulin or other insulin secretagogues (sulfonylureas or repaglinide), hypoglycemia may occur. It is important to remember that this hypoglycemia associated with the use of acarbose or miglitol plus insulin or a insulin secretagogue should be treated with oral glucose (dextrose) and not sucrose or other complex carbohydrates, which may be ineffective. The hydrolysis of sucrose (cane sugar) to fructose and glucose is inhibited by acarbose, and thus products containing sucrose are unsuitable for the rapid correction of hypoglycemia. Patients should be aware of the need to have a readily available source of glucose (dextrose, d-glucose) to treat hypoglycemic episodes. In severe hypoglycemia, intravenous dextrose or glucagon injections may be required.

Gastrointestinal

The most common adverse reactions to acarbose and miglitol are gastrointestinal in nature, including abdominal discomfort, increased flatulence, and diarrhea.^{116,117} These symptoms occur with the highest incidence during initiation of therapy and abate or decrease in intensity with continued use. Roughly 50–60% of patients receiving acarbose and miglitol experience the above adverse GI reactions, which are caused primarily by an increase in gas formation secondary to fermentation of unabsorbed carbohydrate in the large intestine. In clinical studies, increased flatulence has been reported to occur in up to 74% of patients on acarbose versus 29% receiving placebo and in up to 41.5% of patients on miglitol versus 12% receiving placebo. Abdominal pain reported as discomfort occurred in 12–19% of patients on acarbose/miglitol versus 5–9% receiving placebo. Diarrhea occurred in 29–31% of patients on acarbose/miglitol versus 10–12% receiving placebo. Borborygmi may also occur along with flatulence. In clinical trials, the use of antacids or fibrous substances to modify the adverse GI side effects of acarbose has not been successful. Proper dosage titration, however, may help improve patient tolerance of GI-related adverse events (see Dosage above).

Systemic adverse events with acarbose are relatively rare. In one U.S. study, asymptomatic elevations of hepatic enzymes occurred in 3.8% of patients receiving acarbose versus 0.9% of those receiving placebo.¹²⁶ In long-term studies (up to 12 months), elevations of serum transaminases (AST and/or ALT) above the upper limit of normal that required emergency treatment were asymptomatic, reversible, more common in females, and, in general, not associated with other evidence of liver dysfunction. Serum transaminase elevations also appeared to be dose-related, with an increased frequency in those on >300 mg/day. Two patients in Japan died of fulminant hepatitis; however, the relationship to acarbose is unclear.

Miglitol and acarbose are known to decrease iron absorption slightly, but in most cases the reduction in iron indices appears to be clinically insignificant.^{117,139} In clinical trials, low serum iron levels were more commonly noted in patients treated with miglitol

(9.2%) versus placebo (4.2%). In most cases, miglitol was not associated with reductions in hemoglobin or other hematologic indices, and in many cases the effect on iron concentrations was transient. Long-term use of acarbose has also been associated with anemia in roughly 1% of patients. Rare dermatologic findings include an unusual report of serum eosinophilia associated with generalized erythema multiforme and histologic tissue eosinophilia with acarbose therapy.¹⁴⁰ Skin rash (generally transient in nature) also occurred in 4.3% of patients on miglitol versus 2.4% of placebo-treated patients in clinical trials.

Drug Interactions

Digestive enzyme preparations containing carbohydrate-splitting enzymes (e.g., amylase, pancreatin, and pancrelipase) may reduce the pharmacologic effect of α -glucosidase inhibitors (e.g., acarbose or miglitol) and should not be administered concurrently. Since sucrase hydrolyzes sucrose into glucose and fructose, it would antagonize the effects of acarbose or miglitol in the intestine. Charcoal is an intestinal adsorbent that may reduce the effects of the α -glucosidase inhibitors (e.g., acarbose or miglitol) and hence should not be taken concomitantly. It is also possible that concomitant administration of acarbose or miglitol with bile acid sequestrants, such as colestyramine or colestipol, may decrease the effects of these antidiabetic agents. Also, oral neomycin may eliminate gut bacteria responsible for metabolism of carbohydrates and therefore enhance the reduction in postprandial glucose as well as exacerbate GI adverse effects. Clinical documentation of such interactions, however, is lacking. Antacids are not known to affect acarbose action.

α -Glucosidase inhibitors may also impair the oral absorption of digoxin and lead to subtherapeutic serum digoxin concentrations in some patients. Clinical reports of this interaction have been published, but the mechanism of the interaction is not well understood. It is recommended that these agents be administered 6 hours after an oral digoxin dose to ensure time for adequate digoxin absorption.¹⁴¹ In addition, patients should be closely observed for the loss of clinical effect of digoxin therapy if either acarbose or miglitol is added to the medication regimen. In some cases, digoxin serum concentration monitoring may be helpful. Caution should also be exercised in patients on concomitant warfarin therapy, and prothrombin times should be closely observed during the first month of acarbose and miglitol therapy. Any dosage adjustments should be made according to individual patient response.

The combination of acarbose with acetaminophen and ethanol should be avoided since both alcohol and acarbose augment the activity of the hepatic isoenzyme CYP2E1, which is responsible for metabolism of acetaminophen to a toxic reactive metabolite.¹⁴²

THIAZOLIDINEDIONES

The thiazolidinediones or glitazones are oral antidiabetic agents that are also termed *insulin sensitizers*; they act primarily by reducing insulin resistance, which is thought to be central to the development of T2DM and its cardiovascular complications. These agents are chemically and functionally unrelated to the other oral antidiabetic agents. Two compounds in this class are presently approved for use in the United States (Fig. 32–11). Rosiglitazone (Avandia®) was approved on May 25, 1999, and pioglitazone (Actos®) was granted approval on July 16, 1999. The first agent in

FIGURE 32-11. Structure of the thiazolidinediones.

this class, troglitazone (Rezulin®), was marketed in the United States from March 1997 until it was withdrawn in March 2000, when the FDA determined that the risk of idiosyncratic hepatotoxicity associated with troglitazone therapy outweighed its potential benefits. In clinical use so far, rosiglitazone and pioglitazone appear to be devoid of fulminant hepatotoxicity. Monotherapy with the glitazones results in significant improvements in FPG by 59–80 mg/dL and in HbA_{1c} by 1.4–2.6% compared with placebo. Rosiglitazone is approved for use as monotherapy and in combination with metformin and sulfonylurea. Pioglitazone is approved for use as monotherapy and also in combination with insulin, metformin, or a sulfonylurea.

Mechanism of Action

The thiazolidinediones are highly selective and potent agonists for the peroxisome proliferator-activated receptor γ (PPAR γ).¹⁴³ PPARs are a family of nuclear receptors comprised of three subtypes designated PPAR α , PPAR γ , and PPAR δ (previously termed PPAR β , FAAR, or NUC-1).¹⁴⁴ PPAR γ receptors are found in key target tissues for insulin action such as adipose tissue, skeletal muscle, and liver, and evidence to date indicates that these receptors may be important regulators of lipid homeostasis, adipocyte differentiation, and insulin action.^{143,144} A close relationship has been shown to exist between the ability of various thiazolidinediones to stimulate PPAR γ and its antidiabetic action.¹⁴⁵ Most of the studies on the mechanism of action of the glitazones have been done with troglitazone.

Thiazolidinediones have been shown to stimulate GLUT-1 and GLUT-4 gene expression¹⁴⁶ and to reduce ob gene, tumor necrosis factor- α (TNF- α), and hepatic glucokinase expression through activation of PPAR γ .¹⁴⁷ In obese Zucker rats, treatment with the thiazolidinedione troglitazone resulted in a reduction in leptin levels and lower ob gene and TNF- α expression. Associated with this effect was apoptosis of large adipocytes and an increase in the number of small adipocytes (with no net change in adipose tissue weight).¹⁴⁸ Both TNF- α and leptin (an ob gene product) have been associated with insulin resistance, and it is plausible that with the reduction in large adipocytes and lower TNF- α and leptin levels, there is amelioration of insulin resistance. Moreover, the increase in the number of small adipocytes may also contribute to the reduction of insulin resistance. Small adipocytes take up more glucose than large adipocytes at submaximal insulin levels and are also more sensitive to the antilipolytic action of insulin.^{149,150} This

could potentially result in lower FFA and triglyceride levels and improved insulin sensitivity. Although the results from this study suggest that troglitazone exerts potent effects in adipose tissue, another study¹⁵¹ has demonstrated beneficial effects of troglitazone on glucose and lipid metabolism independent of adipose tissue in aP2/DTA mice whose white and brown fat was virtually eliminated by fat-specific expression of diphtheria toxin. In this study, despite the absence of adipose tissue, beneficial metabolic changes were seen in muscle and liver.

In freshly isolated human adipocytes, rosiglitazone increased p85 α -phosphatidylinositol 3-kinase (p85 α PI-3K) and uncoupling protein-2 (UCP) mRNA levels and decreased leptin expression. p85 α PI-3K is a major component of insulin action, and the induction of its expression might explain, at least in part, the insulin-sensitizing effect of the thiazolidinediones.¹⁵² *In vitro*, pioglitazone has been shown to reverse insulin resistance induced by TNF- α in liver cells.¹⁵³

Some studies indicate that the glitazones also have direct effects in skeletal muscle. In human skeletal muscle culture systems, troglitazone treatment markedly increases PPAR γ protein expression along with other genes involved in glucose and lipid metabolism.¹⁵⁴ This increase of PPAR γ and associated changes in other genes may account, in part, for the insulin-sensitizing effect of troglitazone in skeletal muscle. In the same skeletal muscle culture system, troglitazone has been demonstrated to have acute effects on glucose uptake and chronic effects on glucose uptake and glycogen synthase activity.¹⁵⁵ Concomitant increases in GLUT-1 mRNA and protein were noted, with no change in GLUT-4 or glycogen synthase mRNA or protein.

The hypotensive and antiatherosclerotic effects of the glitazones may also occur through PPAR γ agonism.^{156–158} Human and rat vascular smooth muscle cells express mRNA and nuclear receptors for PPAR γ 1.^{156,158} These receptors are upregulated during vascular injury and are present in early human atheroma and precursor lesions. Pharmacologic activation of PPAR γ with troglitazone and rosiglitazone inhibits vascular smooth muscle cell proliferation and migration, with the potential to limit restenosis and atherosclerosis. Also, both troglitazone and pioglitazone inhibit vasopressin and PDGF-induced Ca²⁺ entry and proliferation in rat vascular smooth muscle cells.¹⁵⁶

Thus, the thiazolidinediones act, at least in part, by binding with PPAR γ in various tissues to influence the expression of a number of genes encoding proteins involved in glucose and lipid metabolism, endothelial function, and atherogenesis.^{156–159} In the near future, it is likely that the expression of numerous other genes will be identified that are affected by thiazolidinediones and contribute to the insulin-sensitizing, lipid-lowering, hypotensive, and antiatherosclerotic effects of these compounds.

Pharmacokinetics

After oral administration, both rosiglitazone and pioglitazone are rapidly absorbed, and peak serum concentrations occur within 1 hour for rosiglitazone and within 2 hours for pioglitazone. Food does not alter the pharmacokinetics of rosiglitazone, but it slightly delays the time to peak serum concentration of pioglitazone to 3–4 hours, although total absorption is unchanged. Steady-state serum concentrations of both drugs are achieved within 7 days and are highly protein-bound (>99%), primarily to serum albumin. Rosiglitazone is extensively metabolized, with no unchanged drug detected in urine. The major routes of metabolism include

N-demethylation and hydroxylation, followed by conjugation with sulfate and glucuronic acid. *In vitro* data show that rosiglitazone is predominantly metabolized by the cytochrome P-450 (CYP) isoenzyme 2C8, with CYP2C9 serving as a minor pathway. Metabolites are active but have significantly less activity than the parent compound. On the other hand, pioglitazone is extensively metabolized by hydroxylation and oxidation. The major hepatic cytochrome P-450 enzymes involved are CYP2C8 and CYP3A4. In animal studies, the metabolites M-II and M-IV (hydroxy derivatives of pioglitazone) and M-III (keto derivative of pioglitazone) are pharmacologically active. The metabolites M-III and M-IV are the principal drug-related species found in human serum following multiple dosing. At steady state, serum concentrations of the metabolites M-III and M-IV are equal to or greater than serum concentrations of pioglitazone. The plasma half-life ranges from 3 to 4 hours for rosiglitazone and from 3 to 7 hours for pioglitazone and 16 to 24 hours for pioglitazone metabolites.

Clinical Use and Efficacy

Rosiglitazone is at present approved for use as monotherapy and in combination with metformin and sulfonylureas.¹⁶⁰ In two U.S. placebo-controlled clinical trials in patients with T2DM, rosiglitazone at doses of 4 and 8 mg/day (as a single daily dose or two divided daily doses) for 26 weeks improved FPG by 25–35 and 42–55 mg/dL and HbA_{1c} by 0.3 and 0.7%, respectively, compared with baseline. In these studies, when administered at the same daily dose, rosiglitazone was generally more effective in reducing FPG and HbA_{1c} when administered in divided doses twice daily compared with once-daily doses. However, for HbA_{1c}, the difference between the 4-mg once-daily and the 2 mg twice-daily doses was not statistically significant. In another U.S. study, when compared directly with maximum stable doses of glyburide, rosiglitazone reduced FPG by 25 mg/dL (4 mg/day) and 41 mg/dL (8 mg/day) compared with a reduction of 30 mg/dL for glyburide (15 mg/day). Although the initial fall in FPG was greater with glyburide in this study, the improvement in glycemic control with rosiglitazone was maintained through week 52 of the study. Importantly, in patients treated with rosiglitazone, C-peptide, insulin, and proinsulin levels were significantly reduced compared with an increase of these hormones in the glyburide-treated patients.

The addition of rosiglitazone 2–8 mg/day to existing sulfonylurea, metformin, or insulin therapy also achieves further reductions in FPG and HbA_{1c}. In a double-blind, placebo-controlled trial, 348 patients with T2DM were randomized to receive 2500 mg/g/day of metformin plus either placebo or 4 or 8 mg/day of rosiglitazone. After 26 weeks, compared with the metformin-placebo group, FPG levels decreased by 40 and 53 mg/dL, and mean HbA_{1c} levels decreased by 1.0 and 1.2% in the 4-mg/day metformin-rosiglitazone group and the 8-mg/day metformin-rosiglitazone groups, respectively. Of patients receiving 8 mg/day of metformin-rosiglitazone, 28.1% achieved an HbA_{1c} level of <7%. In addition, β -cell function, measured by the HOMA model, improved significantly with metformin-rosiglitazone therapy in a dose-dependent manner.¹⁶¹ Compared with baseline, the combination of rosiglitazone (2 mg bid) and a sulfonylurea decreases FPG by 38 mg/dL and HbA_{1c} by 0.9% (Fig. 32–12A); in combination with insulin, rosiglitazone at 4 mg bid reduces FPG by 55 mg/dL and HbA_{1c} by 1.3%.¹⁶²

The other currently marketed thiazolidinedione, pioglitazone, is the only glitazone approved by the FDA for use as monotherapy and in combination with sulfonylureas, metformin, and insulin. In

FIGURE 32-12 A. Mean changes in glycemic control at 6 months produced by the addition of rosiglitazone to a sulfonylurea (SU). FPG, fasting plasma glucose; Rosi, rosiglitazone. *, $p < 0.001$ vs. sulfonylurea. (Data from Wolfenbuttel et al.¹⁶²) B. Mean changes in glycemic control at 6 months produced by the addition of pioglitazone (Pio) to a sulfonylurea. *, $p \leq 0.05$ vs. sulfonylurea. (Data from Schneider et al.¹⁶⁴)

the absence of head-to-head studies, it is not possible to evaluate which glitazone is more potent in clinical use. Pioglitazone has been demonstrated to improve glycemia when used as monotherapy. In U.S. studies, after 26 weeks, mean FPG levels were reduced by 30 mg/dL (on pioglitazone 15 mg/day), 32 mg/dL (on pioglitazone 30 mg/day), and 56 mg/dL (on pioglitazone 45 mg/day) compared with an increase of 9 mg/dL in the placebo group. Concurrent with FPG, the HbA_{1c} levels also decreased by 0.3% with pioglitazone 15 and 30 mg daily and 0.9% with pioglitazone 45 mg daily. HbA_{1c} levels increased 0.7% in the placebo group.¹⁶³ In another double-blind study, compared with baseline, pioglitazone 15 and 30 mg daily (when added to a sulfonylurea regimen) reduced FPG by 34 and 52 mg/dL and HbA_{1c} by 0.8 and 1.2%, respectively, after 16 weeks of therapy. In the placebo group, there was an increase of 6 mg/dL in FPG and 0.1% in HbA_{1c}.¹⁶⁴ (Fig. 32–12B). Pioglitazone is also a useful option when used in combination with metformin. In a large 16-week study, compared with placebo, pioglitazone 30 mg daily significantly reduced mean FPG levels by 38 mg/dL and HbA_{1c} levels by 0.8%.¹⁶⁵ Another significant use for pioglitazone is in the treatment of patients on insulin therapy. In a 16-week study, Rubin and coworkers¹⁶⁶ demonstrated that the addition of pioglitazone 15 and 30 mg daily to patients receiving a median daily dose of 60.5 U of insulin resulted in mean FPG reductions of 36 and 49 mg/dL and HbA_{1c} reductions of 0.7 and 1.0%, respectively, compared with placebo.

Other Beneficial Effects

The glitazones have been shown to have multiple beneficial effects not only on peripheral insulin sensitivity, hepatic glucose metabo-

lism, and lipid metabolism, but also on endothelial function, atherogenesis, fibrinolysis, and ovarian steroidogenesis.¹⁵⁹

Effects on Insulin Sensitivity

Most of the human studies on the insulin-sensitizing effects of the thiazolidinediones *in vivo* have been done with troglitazone, which is no longer available. These studies have documented troglitazone's *in vivo* effects on peripheral insulin action not only in patients with T2DM but also in other insulin-resistant states like impaired glucose tolerance (IGT), polycystic ovary disease, previous gestational diabetes, and Werner's syndrome.^{167–172} Some of these studies used the euglycemic clamp and the frequently sampled intravenous glucose tolerance test (FSIGTT) to quantitate changes of insulin sensitivity, whereas other studies used less direct methods, including the insulin tolerance test and the intravenous or oral glucose tolerance test, to assess troglitazone effects on insulin resistance. In all studies, troglitazone in doses ranging from 200 to 600 mg daily enhanced insulin-mediated peripheral glucose utilization in both obese and lean subjects by approximately 30–100%.

Two Japanese studies have documented the insulin-sensitizing effects of pioglitazone in patients with T2DM. In a double-blind, placebo-controlled clinical trial, Kawamori and colleagues¹⁷³ evaluated the effect of pioglitazone on insulin resistance in patients with T2DM. Insulin sensitivity (measured as insulin-stimulated glucose disposal [R_d] by the hyperinsulinemic clamp technique) and splanchnic glucose uptake (SGU) both increased significantly after 3 months of pioglitazone treatment. Placebo treatment produced no significant changes in either R_d or splanchnic glucose uptake. The authors concluded that pioglitazone is effective in ameliorating insulin resistance in T2DM by enhancing splanchnic glucose uptake as well as peripheral glucose uptake.¹⁷³ In another Japanese study, Yamasaki and colleagues¹⁷⁴ also evaluated the effect of pioglitazone on R_d in 20 patients with T2DM. After oral administration of pioglitazone (30 mg/day) for 3 months, in addition to improvement in glycemic control and fasting insulin, C-peptide, and lipid levels, the R_d significantly improved by >50%. In this study, the change in R_d before and after pioglitazone administration correlated with baseline values of FPG ($p = 0.633$), serum insulin ($p = 0.653$), and body mass index ($p = 0.456$).¹⁷⁴ In a recent study in the United States, Miyazaki and colleagues^{174a} demonstrated that pioglitazone therapy for 4 months in obese patients with T2DM significantly improved glycemic parameters and also enhanced hepatic and peripheral (muscle) sensitivity, despite a significant increase in body fat content and body weight of 3.6 ± 1.4 kg (Fig. 32–13).

Effects on Lipids

In T2DM, the major quantitative change in lipid levels is an elevation in triglyceride-rich lipoproteins and a decrease in HDL cholesterol concentrations and LDL cholesterol levels that are often quantitatively similar to that in the general population.¹⁷⁵ However, qualitative changes in the composition of the LDL molecule (including an increase in the proportion of small, dense LDL, which is prone to glycation and oxidation) tend to make it more atherogenic.¹⁷⁵ This diabetic dyslipidemic profile is closely related to underlying insulin resistance and may be partly responsible for the increased cardiovascular morbidity and mortality in T2DM patients.¹⁷⁶ By improving glucose tolerance and reducing insulin resistance, the glitazones have the potential to influence diabetic dyslipidemia favorably. However, from the data presently available,

FIGURE 32-13. Effects of pioglitazone 45 mg daily for 4 months on hepatic glucose production and glucose disposal rate in patients with type 2 diabetes. Open bars, baseline; gray bars, after treatment; *, $p < 0.01$. (Data from Miyazaki et al.^{174a})

there appear to be differences in the lipid-modifying abilities of the various glitazones. Pioglitazone has been shown to lower triglycerides by ~9% and increase HDL levels by ~12–19%.^{177,178} Troglitazone also was shown to lower triglyceride levels by ~15–20%¹⁵⁹ and increase HDL cholesterol levels by ~5–8%.¹⁵⁹

Reduction in triglyceride levels appears to result from several mechanisms, including reduced FFA substrate availability, decreased hepatic triglyceride synthesis, and enhanced peripheral clearance.¹⁵⁹ In the case of rosiglitazone, however, despite a significant decrease in FFA levels by up to 22%, initial studies demonstrated no significant lowering of triglycerides, although HDL levels do increase by up to 19%. The reasons for these differences are not clear at present. In addition, with all the glitazones studied so far, there is an increase in LDL cholesterol levels, which is of concern. In the case of troglitazone, it has been shown that this increase in LDL cholesterol of ~10%¹⁵⁹ occurs without change in atherogenic apolipoprotein B levels.¹⁵⁹ Moreover, following troglitazone treatment, the LDL particles became larger, more buoyant, and less prone to oxidative modification.^{179,180} Data on LDL particle size and apolipoprotein B levels are still not available for rosiglitazone and pioglitazone. Long-term follow-up will be needed to see whether the rise in LDL has a negative impact on atherosclerosis and cardiovascular mortality.

In addition to the above data, one report by Japanese investigators¹⁸¹ found a significant increase in lipoprotein (a) [Lp(a)] levels after 4 weeks of troglitazone treatment at 400 mg daily in a small group of 10 T2DM subjects (despite significant improvements in glucose and insulin sensitivity parameters). No change was found in a control group of sulfonylurea-treated patients. This increase in Lp(a) levels persisted for 12 weeks after discontinuation of troglitazone treatment and then returned to baseline values. Since Lp(a) may be associated with the development of coronary artery disease, further larger, long-term studies are needed to confirm and evaluate the significance of elevated Lp(a) levels in thiazolidinedione-treated diabetic patients.

Effects on Adipose Tissue

At the tissue level, troglitazone has been demonstrated to specifically promote the differentiation of preadipocytes into adipocytes in subcutaneous, but not omental fat.¹⁸² In clinical use, troglitazone at 400 mg/day for 6 months in 30 mildly obese Japanese patients with T2DM not only improved glycemia and increased body mass

index but also resulted in fat accumulation in the subcutaneous rather than the visceral adipose tissue depot. The authors speculated that this shift of energy accumulation from the visceral to the subcutaneous adipose tissue might contribute to troglitazone-mediated amelioration of insulin resistance.¹⁸³ In another double-blind, randomized trial Kelley and colleagues¹⁸⁴ demonstrated that troglitazone therapy for 12 weeks significantly decreased intra-abdominal fat mass as measured by MRI. In this study, there were no significant changes in total body fat and body weight compared with placebo. In a recent study using MRI analysis, Miyazaki and coworkers^{184a} demonstrated that although pioglitazone treatment at 45 mg daily for 4 months was associated with a significant increase in subcutaneous fat area, this was accompanied by a significant decrease in visceral fat area and a concomitant decrease in the ratio of visceral to subcutaneous fat (Fig. 32-14).

Hypertension and Cardiac Function

The prevalence of hypertension in diabetic patients is 1.5–2-fold higher than in nondiabetic individuals,¹⁸⁵ and hypertension is one of the components of the insulin resistance syndrome. In T2DM and other insulin-resistant states, there is impaired insulin-induced vasodilation,¹⁸⁶ and it is possible that by enhancing insulin action, the thiazolidinediones may enhance the tonic vasodilator response to insulin and thereby reduce peripheral vascular resistance and blood pressure. Additionally, by reducing hyperinsulinemia and plasma insulin levels, these agents may reduce the potential blood pressure-raising actions of insulin, such as renal sodium retention and increased sympathetic activity.^{185–188} Limited data show that the glitazones may have beneficial effects on blood pressure. Rosiglitazone 4 mg bid over 52 weeks was associated with a significant decrease in systolic BP of 3.5 mmHg and diastolic BP of 2.7 mm Hg.¹⁸⁹ No data are yet available for pioglitazone.

Effects on Atherogenesis

Increased concentrations and activity of PAI-1 are known to be associated with a prothrombotic state. Levels of PAI-1 are increased in patients with T2DM and are strongly correlated with body mass index, insulin resistance, and fasting levels of insulin, triglycerides, and HDLs.¹⁹⁰ Only troglitazone so far has been shown to decrease PAI-1 levels to near-normal levels in diabetic

patients.¹⁹⁰ Pioglitazone has been shown to decrease PAI-1 levels in cultured human umbilical vein endothelial cells.¹⁹¹ No data are available for rosiglitazone. Platelet aggregation is also increased in diabetic subjects,¹⁹² and only troglitazone so far has been shown to have potent inhibitory effects on human platelet aggregation via suppression of thrombin-induced activation of phosphoinositide signaling in platelets.¹⁹³ This effect was not reproducible with pioglitazone and hence may be due to troglitazone's unique structure, which included an α -tocopherol moiety.

Another factor that is correlated with the pathogenesis and progression of atherosclerosis and restenosis is the proliferation and migration of vascular smooth muscle cells from the media to the intima. Troglitazone and pioglitazone both inhibited vascular smooth muscle cell growth and migration in preclinical studies.^{156,194–196} Also, improvements in vascular reactivity have been shown for troglitazone in human and animal studies and for pioglitazone in animal studies (*in vitro* only).^{197,198}

Intimal-medial thickness (IMT), a measure of atherosclerotic progression, is correlated with insulin levels in patients with and without T2DM.^{199,200} In clinical trials, troglitazone reduced intimal hyperplasia in T2DM patients with and without coronary stent implants.^{199,201} Effects were seen in as little as 3 months and were more profound than previously reported data for pravastatin, an HMG-CoA reductase inhibitor^{202,203} (Fig. 32-15). Pioglitazone has shown similar results in animal studies.²⁰⁴ There is evidence to suggest that IMT is negatively related to insulin sensitivity,²⁰⁵ and it is possible that the reduction in insulin resistance after troglitazone treatment translates to regression of both carotid and coronary IMT. This effect of troglitazone, if confirmed with the other available glitazones and shown to persist in the long term, could be highly beneficial, delaying or preventing development of the accelerated atherosclerosis of diabetes.

Effects on β -Cell Function

An elevated ratio of proinsulin (PI) to immunoreactive insulin (IRI) is often present in T2DM and may reflect dysfunctional β -cell processing of the prohormone and associated reduced β -cell secretory capacity.²⁰⁶ Troglitazone therapy has been shown to be associated with a decrease in the PI:IRI ratio suggestive of direct effects on the β cell.²⁰⁶ In a recent study, rosiglitazone therapy for 52 weeks was shown to decrease significantly the PI:IRI ratio.²⁰⁷ (Fig. 32-16).

Effects on Diabetes Prevention

Consistent with their ability to increase insulin sensitivity and improve insulin secretion, the glitazones have the potential to be used as agents to prevent T2DM. In a recent study, Buchanan and colleagues^{207a} observed that troglitazone at 400 mg daily for up to 5 years reduced the incidence of T2DM by 50% in high-risk Hispanic women with a recent history of gestational diabetes mellitus. Indeed, in the NIH-sponsored Diabetes Prevention Study (DPP), troglitazone along with metformin and intensive lifestyle intervention was one of the intervention arms.⁶⁵ The troglitazone arm was discontinued after reports of idiosyncratic hepatotoxicity associated with its use.

Effects on Cancer Cells

There is preliminary evidence that the thiazolidinediones (through their action on PPAR γ) may have adverse effects on cancer cells. Estrogen biosynthesis is catalyzed by aromatase cytochrome P-450, and adipose tissue is the major site of estrogen biosynthesis in postmenopausal women. Rubin and colleagues²⁰⁸ have demonstrated in tissue culture that the PPAR γ ligands troglitazone and rosiglitazone inhibit aromatase expression in cultured breast adipose stromal cells stimulated with oncostatin M or TNF- α plus dexamethasone in a concentration-dependent manner. This action of PPAR γ agonism may have potential therapeutic benefit in the treatment and management of breast cancer. Takahashi and colleagues²⁰⁹ from Japan have also shown that human gastric cancer cells express PPAR γ and that activation of PPAR γ with troglitazone inhibits cell growth and induces apoptosis in gastric cancer cells. Similar results were obtained by Tsubouchi and colleagues using human lung cancer cells.²¹⁰

On the other hand, there is evidence of tumor-inducing effects of the glitazones in a murine model for familial adenomatous polyposis and sporadic colon cancer. Hence it is recommended that these drugs not be prescribed for people from families with adenomatous polyposis coli.²¹¹ Long-term studies are needed to monitor effects on the development of sporadic colon tumors.

Dosage

The usual starting dose of rosiglitazone is 4 mg po given as either a single dose once daily or in divided doses twice daily. For patients who respond inadequately after 12 weeks of initial treatment with rosiglitazone, the dose may be increased to 8 mg po given as a single dose once daily or in divided doses twice daily. For pioglitazone, therapy may be initiated at 15 or 30 mg po once daily. For pa-

tients who respond inadequately to the initial dose, the dose can be increased in increments up to 45 mg po once daily. Patients not responding adequately to monotherapy with either rosiglitazone or pioglitazone should be considered for combination therapy with other antidiabetic agents. The safety and efficacy of both drugs in adolescents and children have not yet been established.

Patients with Hepatic Impairment

If a patient exhibits clinical or laboratory evidence of active liver disease or increased serum transaminase levels (ALT > 2.5 times the upper limit of normal) at start of therapy, rosiglitazone or pioglitazone therapy should not be initiated (see Contraindications below).

Patients with Renal Impairment

There are no clinically relevant differences in the pharmacokinetics of rosiglitazone or pioglitazone in patients with mild-to-severe renal impairment or in hemodialysis-dependent patients compared with patients who have normal renal function. Hence dosage adjustments are not required in patients receiving these agents alone. However, since metformin is contraindicated in patients with renal impairment, concomitant administration of rosiglitazone or pioglitazone with metformin is also contraindicated in patients with renal impairment.

Side Effects

During double-blind clinical trials, the most frequently reported adverse reactions in nearly 2600 patients receiving rosiglitazone monotherapy included back pain, diarrhea, fatigue, headache, hypoglycemia, hypoglycemia, injury, sinusitis, and upper respiratory tract infection. In pioglitazone-treated patients, the most frequently reported adverse reactions during placebo-controlled clinical trials were headache, hyperglycemia, myalgia, pharyngitis, sinusitis, tooth disorder, and upper respiratory tract infection. Overall, the types of adverse experiences reported when rosiglitazone was used in combination with metformin were similar to those during monotherapy with rosiglitazone. Similarly, when pioglitazone was used in combination with metformin, sulfonylureas, or insulin, the types of adverse experiences reported were similar to those during pioglitazone monotherapy (except for an increase in edema in the pioglitazone-insulin combination study). Overall, the incidence of withdrawal from clinical trials due to an adverse event other than hyperglycemia was similar for patients receiving placebo or a glitazone.

The glitazones increase plasma volume by 6–7%, and edema is often associated with their use. In U.S. clinical trials, edema has been reported more frequently in pioglitazone-treated patients than placebo-treated patients. In monotherapy studies, edema was reported at 4.8% in pioglitazone-treated patients vs. 1.2% of placebo-treated patients; in the pioglitazone-insulin combination study, nearly 15.3% of pioglitazone-treated patients developed edema compared with 7.0% of placebo-treated patients. Edema was also reported in 4.8% of patients receiving rosiglitazone compared with 1.3% on placebo, 1% on sulfonylureas, and 2.2% on metformin. Since an increase in plasma volume can worsen or precipitate congestive heart failure (CHF), patients with Class III and IV CHF should not receive glitazone therapy. Also, all patients on glitazone treatment should be regularly monitored for signs and symptoms of CHF.

Weight gain has also been reported more frequently with glitazone therapy. In the 26-week rosiglitazone clinical trials, the mean weight gain in patients treated with rosiglitazone monotherapy was 1.2 kg (on 4 mg daily) and 3.5 kg (on 8 mg daily). When rosiglitazone was administered in combination with metformin, weight gain was 0.7 kg (on 4 mg daily) and 2.3 kg (on 8 mg daily). There was a mean weight loss of about 1 kg in both placebo and metformin-alone groups in these studies. In the 52-week glyburide controlled study, there was a mean weight gain of 1.75 and 2.95 kg for patients treated with 4 and 8 mg of rosiglitazone daily, respectively, versus 1.9 kg in glyburide-treated patients. Similarly, in clinical studies, pioglitazone treatment is accompanied by weight gain in a dose-related manner. The change in average weight in U.S. placebo-controlled monotherapy trials ranged from 0.5 to 2.8 kg for pioglitazone-treated patients, compared with a weight loss of 1.3–1.9 kg in placebo-treated patients. In combination with a sulfonylurea, the change in average weight was 1.9 and 2.9 kg for 15 and 30 mg of pioglitazone, respectively, and –0.8 kg for placebo. The change in average weight in combination with insulin was 2.3 and 3.7 kg for 15 and 30 mg of pioglitazone, respectively, and no weight change for placebo. Even in combination with metformin, the increase in average weight was 1.0 kg for 30 mg of pioglitazone versus –1.4 kg for placebo.

Due to increases in plasma volume and a dilutional effect, decreases in hemoglobin and hematocrit also occur in a dose-related fashion in patients treated with rosiglitazone and pioglitazone alone or in combination. These changes occur primarily during the first 4–12 weeks of therapy and remain relatively constant thereafter. These changes have not been associated with any significant hematologic clinical effects. Reports of anemia (7.1%) were greater in patients treated with a combination of rosiglitazone and metformin; however, lower pretreatment hemoglobin/hematocrit levels in patients taking metformin concurrently may have contributed to the higher reporting rate of anemia in these studies. For pioglitazone, in U.S. double-blind studies, anemia was reported in 0.3–1.6% of pioglitazone-treated patients and 0–1.6% of placebo-treated patients in monotherapy and combination studies. Rosiglitazone-treated patients also experience slight decreases in white blood cell counts, which may be related to the increased plasma volume.

In controlled trials, 0.2% of patients treated with rosiglitazone had reversible elevations in ALT >3 times the upper limit of normal compared with 0.2% on placebo and 0.5% on active comparator agents. Hyperbilirubinemia was reported in 0.3% of patients treated with rosiglitazone compared with 0.9% treated with placebo and 1% in patients treated with other agents. During placebo-controlled clinical trials in the United States, 4 of 1526 (0.26%) pioglitazone-treated patients and 2 of 793 (0.25%) placebo-treated patients had ALT values >3 times the upper limit of normal. After pioglitazone discontinuation, all patients with follow-up lab values had reversible elevations in ALT. In the population of patients treated with pioglitazone, mean values for bilirubin, AST, ALT, alkaline phosphatase, and GGT were decreased at the final visit compared with baseline. Fewer than 0.12% of pioglitazone-treated patients were withdrawn from clinical trials in the United States due to abnormal liver function tests. In preapproval clinical trials, there were no cases of idiosyncratic drug reactions leading to hepatic failure reported for either rosiglitazone or pioglitazone.

The thiazolidinediones do not stimulate insulin secretion and hence when used as monotherapy are not expected to cause hypo-

glycemia. However, mild-to-moderate hypoglycemia can occur and has been reported during combination therapy with sulfonylureas or insulin. Hypoglycemia was reported for 1% of placebo-treated patients and 2% of patients receiving pioglitazone in combination with a sulfonylurea. In combination with insulin, hypoglycemia was reported for 5% of placebo-treated patients, 8% of patients treated with pioglitazone 15 mg, and 15% of patients treated with pioglitazone 30 mg.

During required laboratory testing in the pioglitazone clinical trials, sporadic, transient elevations in creatine phosphokinase levels without symptoms were observed. A single, isolated elevation to >10 times the upper limit of normal (values of 2150–8610) was noted in seven patients. Five of these patients continued to receive pioglitazone, and the other two patients had completed study medication at the time of the elevated value. These elevations resolved without any apparent clinical sequelae, and the relationship of these events to pioglitazone therapy is unknown.

Drug Interactions

There are significant differences in drug interactions among the glitazones. Both pioglitazone and troglitazone induce the cytochrome P-450 isoform CYP3A4, which is partly responsible for their metabolism. Thus, safety and efficacy could possibly be affected when pioglitazone is coadministered with other drugs metabolized by this enzyme. In contrast, at clinically relevant concentrations, rosiglitazone has no drug interactions with any drugs metabolized by any of the major cytochrome P-450 enzymes. *In vitro* data demonstrate that rosiglitazone is predominantly metabolized by CYP2C8, and to a lesser extent by 2C9. Drugs metabolized by the cytochrome P-450 isoform CYP3A4 include alfentanil, alprazolam, astemizole, carbamazepine, cisapride, some corticosteroids, cyclosporine, diazepam, diltiazem, donepezil, erythromycin, felodipine, fexofenadine, indinavir, lidocaine, lovastatin, midazolam, nifedipine, quinidine, saquinavir, simvastatin, sirolimus, tacrolimus, terfenadine, triazolam, trimetrexate, and verapamil. Blood glucose should be monitored more carefully in patients receiving pioglitazone in combination with the above drugs and also when administered with inhibitors of CYP3A4 such as ketoconazole or itraconazole. *In vitro*, ketoconazole appears to inhibit the metabolism of pioglitazone significantly. It is recommended that patients receiving both pioglitazone and ketoconazole be evaluated more frequently with respect to glycemic control. Studies with itraconazole, which also inhibits CYP enzymes, have not been performed.

Pioglitazone may also reduce the bioavailability of oral contraceptives containing ethinyl estradiol and norethindrone by induction of CYP3A4, and coadministration of pioglitazone with oral contraceptives may reduce the effectiveness of these agents. Oral contraceptive concentrations were reduced by up to 30% with the coadministration of troglitazone. Higher-dosage oral contraceptive formulations may be needed to increase contraceptive efficacy during pioglitazone use. Alternatively, the use of an alternative or additional method of contraception is recommended. On the other hand, multiple dose studies have shown that rosiglitazone has no clinically relevant effect on the pharmacokinetics of oral contraceptives (ethinyl estradiol and norethindrone).

Repeat dosing with rosiglitazone had no clinically relevant effect on the steady-state pharmacokinetics of either warfarin, nifedipine, digoxin, or ranitidine in healthy volunteers, nor did the administration of these medications alter the pharmacokinetics of rosiglitazone. Also in healthy volunteers, coadministration of

pioglitazone with either digoxin, glipizide, metformin, or warfarin for 7 days did not alter the steady-state pharmacokinetics of these medications. Coadministration of acarbose (100 mg three times daily) for 7 days in healthy volunteers had no clinically relevant effect on the pharmacokinetics of a single oral dose of rosiglitazone. A single administration of a moderate amount of alcohol did not increase the risk of acute hypoglycemia in T2DM patients treated with rosiglitazone.

Large doses of aspirin should be used cautiously in patients receiving glitazones. Salicylates inhibit prostaglandin E_2 synthesis, indirectly increase insulin secretion, and in toxic doses may cause hypoglycemia. Also in toxic doses, salicylates may uncouple oxidative phosphorylation, deplete hepatic and muscle glycogen, and cause hyperglycemia and glycosuria acutely. Bexarotene (used in the treatment of cutaneous manifestations of T-cell lymphoma [mycosis fungoides]) may enhance the action of pioglitazone. Patients should be closely monitored while receiving bexarotene in combination with pioglitazone.

Contraindications/Precautions

Troglitazone, the first glitazone marketed in the United States, was associated with idiosyncratic hepatotoxicity and rare cases of liver failure, liver transplants, and death, which led to its recall from clinical use in March 2000. In clinical trials with rosiglitazone and pioglitazone, the incidence of hepatotoxicity and ALT elevations has been similar to that of placebo. In clinical use to date, there have been two reports of hepatotoxicity associated with rosiglitazone use.^{212,213} Thus, although the risk of hepatotoxicity is much lower, it is prudent that rosiglitazone and pioglitazone be used cautiously in patients with hepatic disease, since both rosiglitazone and pioglitazone are structurally very similar to troglitazone.

Liver enzymes should be checked prior to the initiation of therapy with rosiglitazone or pioglitazone in all patients. Therapy with glitazones should not be initiated in patients with increased baseline liver enzyme levels (ALT > 2.5 times the upper limit of normal). In patients with normal baseline liver enzymes, following initiation of therapy with rosiglitazone or pioglitazone, it is recommended that liver enzymes be monitored every 2 months for the first 12 months and periodically thereafter. Patients with mildly elevated liver enzymes (ALT levels 1–2.5 times the upper limit of normal) at baseline or during therapy with rosiglitazone or pioglitazone should be evaluated to determine the cause of the liver enzyme elevation. Initiation of, or continuation of, therapy with a glitazone in patients with mild liver enzyme elevations should proceed with caution and should include appropriate close clinical follow-up, including more frequent liver enzyme monitoring, to determine whether the liver enzyme elevations resolve or worsen.

If at any time ALT levels increase to >3 times the upper limit of normal in patients on therapy with rosiglitazone or pioglitazone, liver enzyme levels should be rechecked as soon as possible. If ALT levels remain >3 times the upper limit of normal, glitazone therapy should be discontinued. If any patient develops symptoms suggesting hepatic dysfunction, which may include unexplained nausea, vomiting, abdominal pain, fatigue, anorexia, and/or dark urine, liver enzymes should be checked. The decision of whether to continue the patient on therapy with rosiglitazone or pioglitazone should be guided by clinical judgment pending laboratory evaluations. If jaundice is observed, drug therapy should be discontinued. There are no data available to evaluate the safety of rosiglitazone or pioglitazone in patients who experience liver abnormalities, he-

patic dysfunction, or jaundice. Neither one should be used in patients who experienced jaundice while taking troglitazone. For patients with normal hepatic enzymes who were switched from troglitazone to rosiglitazone or pioglitazone, a 1-week washout is recommended before starting therapy with either drug.

Caution should also be exercised when using pioglitazone or rosiglitazone in premenopausal anovulatory females with insulin resistance who may resume ovulation as a result of glitazone therapy. These patients may be at risk of becoming pregnant if adequate contraception is not used. In the case of pioglitazone, patients who use oral contraceptive therapy may also be at risk due to CYP3A4 enzyme induction (see above).

Due to increases in plasma volume, both glitazones should be used cautiously in patients with peripheral edema or early congestive heart failure. Rosiglitazone has been associated with preinduced cardiac hypertrophy in animal studies. In two ongoing echocardiographic clinical studies (a 52-week study using pioglitazone 4 mg po twice daily and a 26-week study using rosiglitazone 8 mg po once daily) in patients with T2DM, no deleterious alterations in cardiac structure or function have been observed. These studies were designed to detect a change in left ventricular mass of 10% or more. Patients with severe congestive heart failure, defined as New York Heart Association (NYHA) functional Class III, IV, were not studied. As a result, patients with NYHA Class II heart failure should not receive glitazones unless the expected benefit is judged to outweigh the potential risk.^{160,178}

Rosiglitazone and pioglitazone are contraindicated in pregnancy. Although animal data suggest no teratogenic effects, there are no adequate and well-controlled studies in pregnant women. Also, it is unknown whether these drugs are secreted in human milk, and hence they should not be administered to breastfeeding women.

Thiazolidinediones are only active in the presence of insulin. They should not be used to treat either diabetic ketoacidosis or T1DM.

NEWER ORAL AGENTS

Several new oral agents including insulin secretagogues and insulin sensitizers are being developed for the treatment of T2DM, and many are in the late phases of clinical studies.^{211,214,215} Insulin sensitizers undergoing clinical studies for the treatment of T2DM include several thiazolidinedione and nonthiazolidinedione PPAR α and PPAR γ agonists. These include G1262570 (a Glaxo compound), which is a novel, nonthiazolidinedione, L-tyrosine-based, highly selective PPAR γ agonist. G1262570 is prepared from naturally occurring L-tyrosine and does not contain the 2-4 thiazolidinedione structure common to the other glitazones.²¹¹ (See Chapter 57).

TREATMENT STRATEGIES IN TYPE 2 DIABETES

Insulin resistance is a major abnormality in patients with T2DM, and in addition to hyperglycemia, diabetic patients often manifest hyperlipidemia, hypertension, and a hypercoagulable state. The abnormalities have collectively been referred to as the deadly quartet and comprise the *insulin resistance syndrome* or the *cardiovascular dysmetabolic syndrome*.¹⁰² Hence, in addition to treating hyperglycemia in these patients, we must also strive to ameliorate the other abnormalities of the metabolic syndrome. The goal of

glycemic control is an HbA_{1c} of $\leq 7\%$; the goal for lipid control is $LDL \leq 100$ mg/dL, $HDL \geq 45$ mg/dL, triglycerides ≤ 200 mg/dL (statins are possible first-line agents); the goal for blood pressure control is $<130/85$ mmHg or $120/75$ mmHg (if there is proteinuria; ACE inhibitors are probable first-line agents); and for the hypercoagulable state, all T2DM patients >21 years old should be on aspirin (if not contraindicated).⁴

The first line of therapy for T2DM includes the use of diet management to provide both optimal composition and caloric content so as to assist in achieving desirable body weight. Diet therapy with weight loss is the most effective form of therapy in the obese T2DM patient, but long-term compliance remains poor. Exercise therapy has additional and independent benefits on the metabolic syndrome of diabetes and facilitates the success of diet. When diet, exercise, and weight loss are unable to achieve the glycemic goals outlined above, the usual next step is to proceed to oral antidiabetic medications, alone or in combination. When adequate glycemic control cannot be achieved with oral agents, insulin is then added or substituted as sole therapy.

Monotherapy

The choice of initial oral agents in patients with diabetes is dictated by many factors including patient profile, initial level of hyperglycemia, and economic and formulary considerations (Fig. 32-17 and Table 32-4). A summary of the reported glucose-lowering effects of monotherapy is given in Table 32-5. Since these were not simultaneous trials, the comparative data are only a rough approximation of the relative effectiveness: Stage, severity of hyperglycemia, and type of patient studied varied.

In general, patients with marked hyperglycemia (>300 mg/dL), ketonuria, or ketonemia, pregnant patients, and patients with acute myocardial infarction and all acute situations should all be treated with insulin. In most other patients, a sulfonylurea (in lean patients) or metformin (in obese patients) may be initiated and titrated upward every 1–2 weeks depending on the response. It is extremely important that patients regularly monitor their fingerstick blood glucose. The goal for fasting capillary blood glucose is between 80–120 mg/dL and that of postprandial capillary blood glucose 100–140 mg/dL. In elderly patients and those with irregular meal profiles, a short-acting secretagogue like repaglinide may be preferable to a sulfonylurea, which may cause hypoglycemia with missed meals. In those with predominant postprandial hyperglycemia, acarbose or miglitol may be good choices. Obese patients with renal insufficiency may be started with a glitazone instead of metformin, which is contraindicated in these patients. Some of the other metabolic effects of the oral antidiabetic agents used as monotherapy are shown in (Table 32-6).

Unfortunately, due to the progressive nature of T2DM and the continued decline in β -cell function, monotherapy eventually fails to provide adequate glucose control in most patients with T2DM and combination therapy is frequently a necessity,⁵ especially if one is to achieve optimal glycemic control ($HbA_{1c} < 7\%$). In the UKPDS, the progressive deterioration of glucose control was such that after 3 years, only about 50% of subjects attained a goal of $HbA_{1c} < 7\%$ with monotherapy, and after 9 years this declined to $<25\%$ (Fig. 32-18). It is important to rule out first the possibility that secondary treatment failure is due to noncompliance; doing so will avoid the need for additional agents.

There is also an emerging concept that it may be advantageous to begin combination therapy earlier in the course of the disease

rather than escalate the dose of a single current agent in order to achieve greater glucose-lowering effect. Such a practice is based on the belief that therapy directed at more than one mechanism of action may provide more rapid, sustained, and cost-effective glycemic control. Further studies will be necessary to confirm the clinical utility of this practice.

Combination Therapy

The goal of combination therapy is to take advantage of the differing mechanisms of action of the various pharmacologic agents and create an individualized treatment plan for achieving effective glycemic control. The combination of two agents often results in a synergistic rather than a mere additive glucose-lowering effect. In some cases, lower doses of both agents can be used, which can further minimize side effects. Oral combination therapy is advantageous because it can often delay the need for insulin. Ideally, combination therapy should be instituted prior to manifestation of hyperglycemic symptoms. A comparison of some of the trials is shown in Table 32-7. It must be emphasized that heterogeneity of patients and severity and stage of disease make comparisons only approximate.

Combination of an Insulin Secretagogue and an Insulin Sensitizer

The combination of a secretagogue and an insulin sensitizer is synergistic and addresses two of the major pathophysiologic abnormalities in T2DM. If monotherapy with a sulfonylurea or metformin fails to achieve the desired level of glycemic control, the other second oral agent (if not contraindicated) should be added, with dose escalation over 4–8 weeks to the maximum. Indeed, the use of a sulfonylurea plus metformin is the most widely and extensively studied combination of oral agents and lowers HbA_{1c} by an additional 1.7%.⁹¹ The combination of a sulfonylurea and a glitazone is also useful. The addition of rosiglitazone 4 mg bid to a sulfonylurea resulted in a reduction of FPG by 38 mg/dL and the HbA_{1c} by 0.9% over 6 months.²¹⁶ Similarly, pioglitazone 30 mg daily, when added to a sulfonylurea, decreased FPG by 52 mg/dL and HbA_{1c} by 1.2% after 26 weeks.²¹⁷

When a glitazone is used in combination with a sulfonylurea, the current dose of the sulfonylurea should be continued, and the glitazone should be initiated at the lowest dose. If the response is not adequate, the dose can be increased after approximately 2–4 weeks to the maximum. If patients experience hypoglycemia in combination with a sulfonylurea, the sulfonylurea dose may be lowered as necessary to optimize therapy. The addition of the non-sulfonylurea secretagogue repaglinide to metformin has also been shown to confer significantly better glycemic control than monotherapy with either agent. With combination treatment, mean FPG decreased 39 mg/dL and mean HbA_{1c} levels decreased 1.4% from baseline, compared with decreases of 5–9 mg/dL and 0.3–0.4% on therapy with either agent alone.²¹⁸ There are no studies evaluating the efficacy of repaglinide in combination with pioglitazone or rosiglitazone.

Combination of Two Insulin Sensitizers

Since both metformin and the glitazones act through different mechanisms, their combination may be expected to be more efficacious. Moreover, since metformin predominantly restrains hepatic glucose production and the glitazones act primarily on insulin resistance in muscle and adipose tissue, their combination also ame-

FIGURE 32-17. Algorithm for the treatment of type 2 diabetes. FPG, fasting plasma glucose.

liorates two major pathophysiologic abnormalities in T2DM. The combination of metformin and rosiglitazone 8 mg daily for 26 weeks reduced FPG by 54 mg/dL and HbA_{1c} by 1.3% compared with placebo.¹⁶⁰ The combination of metformin and pioglitazone 30 mg daily decreased FPG by 38 mg/dL and HbA_{1c} by 0.8% compared with placebo, after 26 weeks.¹⁷⁸

Other Oral Combinations

The addition of acarbose to sulfonylurea or metformin therapy represents another option for improving glycemic control in patients with T2DM, particularly those with significant postprandial hyperglycemia; it also lowers HbA_{1c} a further 0.5–1%.²¹⁹ It should be reiterated that although acarbose monotherapy does not caus

TABLE 32-4. Oral Antidiabetic Agents as Initial Monotherapy

Agent	Major Mechanism(s) of Action	Most Suitable Patient Profile	Glycemic Benefit
Insulin secretagogues			
Sulfonylureas	↑↑ Day-long pancreatic insulin secretion	Lean/insulinopenic	Fasting and postprandial glycemia
Meglitinides	↑↑ Postprandial pancreatic insulin secretion	Lean/insulinopenic	Postprandial glycemia

hypoglycemia, combination with sulfonylureas may increase the hypoglycemic potential of the sulfonylurea. This hypoglycemia should be treated with dextrose, and not sucrose, which, as mentioned earlier, may not be effective.

Some physicians may choose to add bedtime insulin to oral agent monotherapy rather than add a second oral agent. However, it has been shown that the addition of metformin to ongoing sulfonylurea therapy in patients experiencing secondary failure achieves reductions in FPG and HbA_{1c} that are not statistically different from those achieved with the addition of insulin to the current therapy or complete switchover to insulin.²²⁰ Thus, use of this combination may delay the need to use insulin.

If combination therapy with two oral agents does not achieve the desired goal, available options include (1) adding a third oral

agent; (2) adding bedtime insulin while maintaining therapy with one or both oral agents; or (3) switching the patient to a mixed-split (short-acting plus long-acting insulin given in two to four daily injections) insulin regimen.²²¹ Although the use of combination therapy may require greater patient adaptability and compliance, most patients would prefer combination therapy to the alternative of exclusive insulin use. Thus, it is important to individualize therapy on the basis of patient preferences.

Triple Oral Combination Therapy

The combination of a sulfonylurea, metformin, and a glitazone, or a sulfonylurea, metformin, and acarbose, is often used in clinical practice. The unique mechanisms of action of these agents can potentially complement each other to improve glycemic control in patients with T2DM. This combination may obviate the need for insulin therapy, but issues of effectiveness, cost, benefit, and compliance have yet to be determined. Future studies will be required to test the efficacy of these various combinations.

Adding Insulin to Oral Therapy

In the not-so-distant past, patients who were not adequately controlled with sulfonylureas were switched over to insulin exclusively. Numerous studies in the late 1980s and in the early part of this decade demonstrated a modest yet significant improvement in glycemic control with combined sulfonylurea-insulin therapy over that seen with insulin alone.^{222,223} Continuation of the sulfonylurea in this instance resulted in better glycemic control, primarily owing to the effect of evening insulin in restraining hepatic glucose output during the night and early morning periods (a characteristic feature of T2DM). Once fasting hyperglycemia is controlled, it appears that the daytime sulfonylureas are better able to maintain daytime postprandial glycemia. The use of these two agents simultaneously allows one to start with a low dose of insulin and results in better glycemic control during the transition. Combination sulfonylurea-insulin therapy also reduces the day-to-day variability in fasting glucose levels compared with a single insulin injection.

The addition of intermediate insulin at bedtime to ongoing sulfonylurea therapy has been shown to offer glycemic control comparable to that of various insulin regimens and insulin-sulfonylurea combinations.²²⁴ Moreover, administration of insulin at bedtime resulted in less weight gain and reduced hyperinsulinemia. This regimen, known as bedtime-insulin/daytime-sulfonylurea (BIDS) therapy, may be better than daytime insulin therapy because hepatic glucose overproduction is typically most abnormal during the night.

Patient selection is an important determinant in the success of a BIDS regimen and is more likely to be successful in obese patients who have been diagnosed with diabetes after the age of 30, have had diabetes for less than 10–15 years, and have glucose values consistently <250–300 mg/dL. To implement BIDS therapy, the patient's current sulfonylurea therapy is continued, and intermediate-acting insulin (0.1–0.2 U/kg) is administered at bedtime (usually 9–11 PM). The insulin dose is adjusted until the morning FPG level is <120 mg/dL. The sulfonylurea dose should be reduced if daytime hypoglycemia is a problem. Patients who continue to experience hyperglycemia before supper despite acceptable fasting glucose levels may require a switch to multiple insulin injections and discontinuation of the sulfonylurea. There are few, if any, apparent benefits to maintaining sulfonylurea when patients are on multiple doses of insulin. The above regimen is also suitable for use in those patients who have failed a combination of a sulfonylurea and metformin. Metformin is retained in this regimen since its insulin-sparing effect, along with its favorable effect on the lipid profile, may be beneficial in ameliorating cardiovascular risk.

Adding Oral Agents to Insulin Therapy

If the oral agent-insulin combination therapies described above fail, the patient is typically switched over to insulin exclusively; intermediate-acting insulin (NPH or Lente[®]) may be administered twice daily (morning and bedtime). However, a combination of intermediate-acting and regular insulin (morning and supper) is more commonly used for optimal control. In some cases multiple (three or more) injections may be necessary to achieve acceptable glycemic control. Several specific insulin regimens to treat T2DM are available.²²¹

Until recently, the only option for patients not adequately controlled with insulin was to increase their insulin dose. However, this practice further increases the likelihood of hyperinsulinemia and weight gain. There has been ongoing research in this area, and it appears that adding oral agents such as acarbose, metformin, or glitazone to insulin therapy—alone or in combination—is a feasible way of improving or normalizing glycemic control in a significant number of patients^{224a} (Fig. 32-19). It may even be possible to discontinue insulin therapy in selected patients and reinstitute combination oral hypoglycemic treatment.

Insulin and Metformin

Metformin may be a useful adjunct in patients poorly controlled with insulin after sulfonylurea agents have achieved

FIGURE 32-19. Improvement in glycemic control (change in HbA_{1c}) with the addition of various oral agents to insulin therapy in patients with type 2 diabetes. *, $p < 0.05$; †, $p < .07$, compared with insulin only. (Data from Mudaliar et al.²²¹)

maximal effect. In these patients, metformin offers an advantage in that it does not stimulate insulin secretion and thereby exacerbate hyperinsulinemia. Metformin also does not contribute to weight gain, which can exacerbate insulin resistance. In a recent study in 96 patients with T2DM poorly controlled with oral sulfonylurea therapy, Yki-Jarvinen and colleagues²²⁵ demonstrated that combination therapy with bedtime insulin plus metformin not only prevents weight gain but also seems superior to other bedtime insulin regimens with sulfonylureas with respect to improvement in glycemic control and frequency of hypoglycemia.

In a patient on a full insulin regimen achieving suboptimal glycemic control, one can attempt to initiate and titrate metformin up to 500 mg three times a day. If the FPG remains <120 mg/dL consistently, the dose of metformin can be further increased gradually to a maximum of 850 mg three times a day (or 1000 mg twice a day). If glycemic control is adequate (FPG remains <120 mg/dL on 2 consecutive days), one can attempt to reduce the dose of insulin by 25% and closely monitor blood glucose values for decompensation. If this occurs or if glycemic control is not adequate on the maximum dose of metformin and lower doses of insulin, there is the option of adding a once-daily sulfonylurea (glipizide extended release or glimepiride) and titrating the dose as required. The addition of a glitazone and acarbose to the above regimen also remains an option to the alternative of exclusive insulin treatment. The issues of cost effectiveness and compliance remain to be determined.

Insulin and Acarbose

The addition of acarbose to insulin therapy may be an option when postprandial hyperglycemia continues to be a problem. Chiasson and colleagues²¹⁹ demonstrated a decrease in HbA_{1c} of 0.4% by acarbose in patients poorly controlled on insulin therapy. Acarbose may be initiated in patients on insulin treatment by starting with a low dose of 25 mg with breakfast and titrating up by 25 mg weekly to 50–100 mg three times daily with meals (100 mg tid dose for patients >60 kg in weight), depending on GI tolerance and efficacy.

Insulin and a Glitazone

Glitazones primarily improve insulin sensitivity and thus are well suited for use in insulin-resistant patients with T2DM. In a 26-week, placebo-controlled study,²²⁶ the addition of 4 mg bid of rosiglitazone to insulin therapy in patients poorly controlled on insulin alone (HbA_{1c} $\sim 9\%$) resulted in a significant reduction of FPG by 44 mg/dL (42 mg/dL on 2 mg bid) and HbA_{1c} by 1.2% (0.6% on

2 mg bid) compared with baseline. In addition, there was a reduction in insulin dose by 9 U on 4 mg bid (5 U on 2 mg bid). The addition of pioglitazone also results in similar reductions.²²⁷ After 16 weeks, the combination of 30 mg of pioglitazone and insulin decreased FPG by 48 mg/dL (35 mg/dL on 15 mg/day) and HbA_{1c} by 1.26% (1% on 15 mg/day). All patients remained on a median of 60.5 U of insulin daily.

When initiating glitazone treatment in T2DM subjects on insulin and suboptimal glucose control, the current insulin dose should be continued, and the lowest dose of a glitazone (4 mg of rosiglitazone or 15 mg of pioglitazone) should be added once daily. If FPG levels remain consistently above 120 mg/dL, the dose of the glitazone should be increased every 2–4 weeks, up to a maximum of 8 mg daily for rosiglitazone and 45 mg daily for pioglitazone until FPG levels are consistently within the target range. At that time, one may attempt to lower the total daily dose of insulin by 10–25%. It must be mentioned here that at the present time, rosiglitazone is not approved by the FDA for use in combination with insulin. Increased weight gain has been observed with this combination.

Reinitiation of Oral Therapy in Insulin-Treated Patients

The recent availability of newer oral antidiabetic agents has allowed the possibility of discontinuing insulin treatment and reinitiating oral agents in selected patients with T2DM. This therapeutic strategy, however, is still under investigation. In a recent pilot study, out of 55 patients with T2DM who were on twice-daily insulin treatment for <10 years and had a random C-peptide level >0.8 ng/mL, 42 patients were successfully able to switch over to a combination of glyburide and metformin and discontinue insulin treatment.²²⁸ This change to a combination of oral agents was accomplished with significantly better glycemic control (a decrease in HbA_{1c} of 1.3%) and decrease in body weight (5 lbs) over 6 weeks. In this study,²²⁸ significant factors predicting a successful switch to oral agents in the responders included a lower body mass index ratio (30 versus 34.8), lesser duration of insulin treatment (5.0 versus 8.6 years), and lesser total daily dose of insulin (0.8 versus 1.2 U/kg body weight).

CONCLUSIONS

Until 1994, the pharmacologic management of T2DM (non-insulin-dependent diabetes mellitus [NIDDM]), as it was then called) was quite straightforward. Only two classes of agents were available. Upon initial diagnosis, a sulfonylurea was prescribed, and when patients became too symptomatic or were markedly hyperglycemic, insulin treatment was added or substituted. In the last 6 years, however, two major developments have occurred. First, we now have unequivocal evidence from major long-term studies like the UKPDS that tight control of hyperglycemia in T2DM has significant benefits on the prevention and progression of microvascular and possibly macrovascular disease. Second, to achieve this optimal control, several new classes of oral antidiabetic agents have become available for use as monotherapy: insulin secretagogues (sulfonylureas, repaglinide, nateglinide), biguanides (metformin), α -glucosidase inhibitors (acarbose and miglitol), and thiazolidinediones (rosiglitazone and pioglitazone). However, T2DM is a progressive disease, and over the years tight control of blood glucose often involves combination therapy as a means of optimizing

glycemic control. Combinations of oral agents can often delay the need for insulin. Oral agents can also be used in combination with insulin to aid in achieving glycemic goals and reducing hyperinsulinemia.

Which combination of oral agents or insulin is more beneficial is at present not clear, and studies to answer this question are in progress. Several new insulin sensitizer agents are also in development, and the feasibility of inhaled or even buccal insulin may soon become a reality. The ultimate objective, of course, is the prevention of diabetes. The Diabetes Prevention Program is looking into this very question and has randomized more than 3000 subjects into either an intensive lifestyle arm, a placebo arm, or a metformin treatment arm.⁶⁵ The finding of a significant preventive effect of lifestyle and metformin have indicated that delay and perhaps prevention is possible.^{65a,66} This outcome is exciting indeed for those who take care of patients with T2DM and even more hopeful for those at high risk for the disease.

Behavioral and Family Aspects of the Treatment of Children and Adolescents with Type 1 Diabetes

Margaret Grey

William V. Tamborlane

Type 1 diabetes mellitus (T1DM) is a complex metabolic disease that requires constant attention from the patient, the family, and the provider to achieve treatment goals. Even before the results of the Diabetes Control and Complications Trial^{1,2} were available, treatment of diabetes was thought to be difficult and onerous for families. Since release of the DCCT findings, the standards of care as published by the American Diabetes Association³ recommend that all children be treated with intensive therapy, with the goal of achieving levels of metabolic control as close to normal as possible, so as to delay and/or prevent the development of the long-term complications of diabetes. Intensive therapy, which involves frequent blood glucose monitoring, three or more injections of insulin per day or use of continuous subcutaneous insulin infusion (CSII), carbohydrate counting, and more frequent visits to health care providers, thus requires a significant effort on the part of the patient and family to achieve treatment goals. Furthermore, those who are most successful in achieving treatment goals may be most at risk for the acute complications of intensive treatment—severe hypoglycemia and clinically significant weight gain. Finally, the occurrence of a chronic illness such as type 1 diabetes in a developing child may put the child and family at significant risk for the development of behavioral and social problems.^{4,5} Thus, T1DM in childhood has the potential to have a significant negative impact on the developing child and the family. Conversely, the challenges provided by diabetes may strengthen and enhance adaptive behaviors in the child and the family.

DEVELOPMENTAL AND FAMILY ISSUES IN T1DM

Two developmental progressions are important in children with diabetes. Type 1 diabetes progresses through four distinct stages: diagnosis, partial remission or the honeymoon period, intensification, and total diabetes care. Furthermore, children and adolescents themselves are developing through several phases: infancy and young childhood (up to 5 years of age), school-age and preadolescent (6–11 years), adolescent (12–18 years), and young adults (19–24 years). According to Erikson's⁶ psychosocial theory, the developing person experiences a crisis at each life stage that may result in a positive outcome and transition to the next phase of psychosocial development, or a negative outcome. These developmental phases interact with the phase of the disease and both must be con-

sidered in managing children with diabetes and their families, as shown in Table 33-1. In addition, developmental status might impact on the effectiveness as well as the appropriateness of various interventions.

Infancy and Young Childhood

Diabetes in infants is relatively rare; nonetheless it does occur, with less than 1.5 cases per 100,000 reported.⁷ According to Erikson the major psychosocial task of infancy is "Trust versus Mistrust." During this phase, the infant must develop a foundation of trust of the world, and this trust is established primarily through the establishment of a relationship with a dependable caregiver. The infant needs to learn to trust the environment that surrounds him or her through learning to trust the mother or primary caregiver. This task becomes extremely difficult when painful injections and fingersticks are a consistent part of the infant's day. The mother may also report anxiety at the thought of causing pain to her own infant. Cognitively, the infant learns to separate self from others and learns basic trust in the world.⁸ The infant lacks the cognitive ability to understand that painful procedures are necessary and in the best interest of the child. For the infant, both the hospitalization and the ongoing treatment disrupt home routines that are so important in establishing trust. These events interfere with the infant's efforts to master the developmental tasks of behavioral organization and regulation and basic trust. Thus it is extremely important for caregivers to establish ritualistic routines for infants with diabetes that enhance the development of regulation and trust.

These developmental issues are often compounded since the diagnosis of diabetes may be delayed in infants, and when the diagnosis is made, the infant may be quite ill. In addition to the crisis engendered by the serious illness and hospitalization of their infant, parents must now adapt to the diagnosis and learn the myriad skills of daily management. The tremendous responsibility of care and fear of hypoglycemia is extremely stressful for young families.⁹ Banion and colleagues⁹ found that the younger the child with diabetes, the greater the concern about hypoglycemia. Since infants do not exhibit the classic catecholamine response to hypoglycemia and are unable to communicate sensations associated with hypoglycemia, the risk of severe hypoglycemia, with seizures or coma, is highest in this age group. Moreover, since the brain is

TABLE 33-1. Major Developmental Issues and Their Effect on Diabetes in Children and Adolescents

Developmental Stage	Developmental Issue	Diabetes Management Issues	Psychosocial Complications
Infancy	Trust vs. Mistrust	Hypoglycemia	Failure to gain trust
Toddler	Autonomy vs. Shame and Doubt	Toilet training	Discipline
		Fear of hypoglycemia	Temper tantrums
		Irregular food intake	Burden on families
Preschooler	Initiative vs. Guilt	Child care	Magical thinking
		Unpredictable activity	Regression
School-age	Industry vs. Inferiority	Beginning participation in self-care	Depression, withdrawal
		Cognitive effects of hypoglycemia	Peer acceptance
Adolescence	Identify vs. Role Confusion	Rapid physical growth	Rebellion, family conflict
		Insulin resistance	Depression
		Lack of self-care	Eating disorders

still developing in infants, the adverse consequences of severe hypoglycemia are also greater than in older children. Parents struggle with the balance between the risk of long-term complications versus their fear of severe hypoglycemia and the risk of neuropsychological complications.

During the toddler years, ages 1–3, the diagnosis of type 1 diabetes is more common, although the incidence is still fairly low compared to older age groups. The toddler's major psychosocial task is to develop a sense of autonomy.⁶ As toddlers develop more control of their bodies, they begin to explore and experience various aspects of the world. Erikson suggested that if the toddler is not allowed to develop this sense of autonomy and power over the environment, a sense of shame and doubt can develop. This achievement of autonomy relates primarily to the accomplishment of toilet training and mobility, and if diabetes control is not optimal, toilet training may be delayed. Toddlers love to explore and need to be given the freedom, within limits, to explore their world. In terms of cognitive skills, toddlers are able to participate in diabetes care minimally, choosing a finger for a fingerstick, for example. Because they don't understand the need for painful procedures, toddlers are extremely frightened of them. To begin to understand their autonomy, toddlers must begin to incorporate the knowledge of their illness into their emerging sense of self. The toddler begins to experience a sense of power that he or she can effect change in the environment. This sense of power may be reflected in temper tantrums and other behaviors that are indicative of a refusal to cooperate. Especially problematic at this age are the finicky eating habits and food jags associated with this age group.

As with infants, parents carry the burden of management of toddlers totally. Parents also report that hypoglycemia is a constant fear, especially when the child refuses to eat. An important issue at this age is discipline and temper tantrums. It is difficult for a parent to tell the difference between normal developmental opposition and hypoglycemia, and therefore the parent must be taught to check blood sugar before ignoring a temper tantrum. Parents may be overly cautious and interfere with the child's ability to try out new things.

Preschoolers (age 3–5) need to accomplish what Erikson called "Initiative versus Guilt."⁶ In other words, they need to gain confidence in their ability to accomplish certain tasks. Cognitively, their style is preoperational and characterized by magical thinking.⁸ This developmental stage involves a child's explanations, perceptions, and imaginations of the world. Because of their limited understanding, children may associate the illness or its painful

treatment with punishment; in other words, they have diabetes because they were bad. Further, the child believes that the illness can be cured at any time magically by an adult. These factors may contribute to a child developing guilt rather than initiative. Energetic learning helps to promote the child's sense of purpose and direction, giving him or her a sense of accomplishment and satisfaction with activities. If diabetes is diagnosed during the preschool years, the child may regress to clinging, bedwetting, or nightmares. Assisting them to maintain their self-esteem by continuing usual activities and rewarding positive behaviors can be helpful. Preschoolers want to please others. They have boundless energy, but still lack the fine motor control necessary to be an active participant in most diabetes care.

For the most part, parents provide the care for preschoolers, but others, such as child care providers, may be involved in the care. Sharing care of young children with diabetes is often difficult for parents, who may fear that others will not know what to do.⁹ Parents of preschoolers have similar anxieties and frustrations as those of younger children. Undetected hypoglycemia remains a concern because of the variations in activity associated with this age group, as well as the unpredictable appetite and food choices, and because of continuing concerns regarding the adverse effects of hypoglycemia on brain development and function.

School Age

Diabetes is the most common endocrine disorder of middle childhood.¹⁰ Thus the incidence of diabetes in school-age children is substantially higher than in earlier age groups. In this stage, which Erickson calls "Industry versus Inferiority," school-aged children strive to develop a sense of industry at school and at home.⁶ The child is involved in new ideas and tasks or takes on a sense of inferiority in which he or she feels incapable of accomplishing anything. Between the ages of 7 and 11, the child is better able to think, learn, remember, listen, and communicate.⁸ Cognitive processes are becoming more logical and less egocentric. They are learning concrete cognitive operations; they now understand rules and follow them closely. They are able to deal with symbols and begin to master classifications. As children deal with the challenges of school, they begin to turn their attention away from the home environment, and the peer group becomes more important. Each of these skills may affect the adaptation to diabetes.

Several authors have examined the influence of the new diagnosis of diabetes on children in this age group. Kovacs and col-

leagues¹¹ studied a cohort of school-aged children with newly diagnosed diabetes for 6 years and found that during the 6 months after diagnosis, children reported mild depression and anxiety, but these usually resolved by 6 months after diagnosis. They also found that after the first year, there was an increase in depressive symptoms, and anxiety decreased for boys but increased for girls over the first 6 years after diagnosis.¹¹ Similarly, Grey and colleagues⁴ found that after an initial period of adjustment characterized by depression and mild anxiety, children with newly diagnosed diabetes were psychosocially similar to age- and gender-matched peers until the period between 1 and 2 years post-diagnosis, when depression markedly increased in the diabetes group. This increase in depression may be associated with the end of the physiologic honeymoon period as well as with the stage of psychosocial adjustment to the disease, when children come to realize that the disease will not go away and that it is more difficult to manage.

Both longitudinal and cross-sectional studies have suggested that school-age children with diabetes may have difficulties in psychosocial adjustment. In general, the majority of children will do well, but diabetes may become a risk factor for the development of psychosocial difficulties in a relatively small percentage of children, often estimated at approximately 10–20%.⁵ In most studies of overall adjustment, however, children with diabetes were found to score within the normal range or similarly to age- and gender-matched controls in such areas as behavior,¹² temperament,¹³ and self-competence and self-esteem.^{4,11} In those who do demonstrate psychosocial difficulties in the school-age years, children tend to be more depressed, withdrawn, and quiet, and their metabolic control may also be compromised.⁴

Although the majority of children do well, some children have difficulty, and researchers have examined several areas that may help to predict those children. How children cope with having diabetes as well as other stressors in their lives has been investigated in a number of studies. Kovacs and her colleagues¹¹ reported that during the first year after diagnosis, children used instrumental and problem-focused coping strategies, including seeking diabetes-related information. Early in the course of the illness, these authors did not find a correlation between coping behaviors and psychologic adjustment. On the other hand, Grey and associates¹⁴ found that behaviors and lack of self-care of the diabetes were associated with poorer psychosocial adjustment 1 year after diagnosis.

The complexity of the diabetes regimen requires adherence to a multitude of tasks. There have been several studies that examined adherence to the diabetes regimen in school-age children with diabetes. In a study of an onset cohort of children with diabetes, initial assessment of patient coping was found to be associated with the level of patient adherence over 4 years of study.¹² Coping strategies, such as problem-focused coping, contributed significantly to treatment responsibility among children with diabetes, and higher levels of avoidance coping were associated with poorer metabolic control.¹⁵

Another factor associated with regimen adherence is the involvement of the family. Earlier approaches to diabetes management advocated early transition of care responsibilities to children with diabetes. Fonagy and coworkers¹⁶ studied factors associated with poorer metabolic control and found that a child's early and independent participation in the diabetes regimen was significantly associated with poorer control. This finding was replicated in a

later study,¹⁷ so that current recommendations for care emphasize shared care responsibilities between parents and children.

It is clear that the diagnosis of diabetes in a child has a significant impact on parents and families. As part of their prospective study of school-aged children with newly diagnosed diabetes, Kovacs and associates¹⁸ interviewed parents as well as children and found that the initial strain of living with diabetes elicited mild and subclinical depression, anxiety, and overall distress, especially in mothers. By the end of the first year, most mothers came to terms with the diabetes, and other areas of parental functioning such as the quality of the marriage were not affected. Nonetheless, parents remain concerned with their ability to manage the diabetes regimen and cope with restraints imposed by the illness, and this coping has psychological effects, such as anxiety and depression, on the parents.

Such parental distress may be associated with child adjustment, demonstrating the transactional nature of relationships in these families.¹⁹ Parental conflict, cohesion, and organization in the first year after diagnosis have been found to be associated with adherence to the diabetes regimen in children.²⁰ Furthermore, as children age, the influence of family and parental environment on metabolic control may decrease.

Both children and parents fear hypoglycemia and the potential for hypoglycemia to interfere with learning. Even mild hypoglycemia causes acute alterations in cognitive function, especially associative learning, attention, and mental flexibility.²¹ A single episode of hypoglycemia causes both lower plasma glucose thresholds for autonomic activation and symptoms and lower nadir plasma glucose concentrations during moderate hyperglycemia.²² Thus the potential for further acute events increases. Cognitive deficits associated with the acute phase of hypoglycemia include transient reduction in mental efficiency, altered electroencephalogram, and increased regional cerebral blood flow.²³ There is some evidence that some cognitive deficits persist beyond the acute phase. Several investigations have found that while diabetes itself is not associated with cognitive deficits, cognitive dysfunction may be increased in children and adolescents who have experienced severe hypoglycemia.^{24,25} Recent data suggest that some of the learning difficulties in children who have experienced severe hypoglycemia earlier in life may be due to difficulties in delayed spatial memory.²⁶ In addition, the occurrence of hypoglycemia leads to fear of the next episode of hypoglycemia. Researchers have suggested that fear of hypoglycemia is a legitimate consequence of hypoglycemia in children and that the aversive nature of severe hypoglycemia may lead patients and parents to institute behavioral changes to maintain higher blood glucose, overtreatment of initial symptoms, and poorer metabolic control. Further, fear of hypoglycemia may be associated with poorer psychological status and adaptation as well.²⁷ For some children, the ability to use avoidance behaviors, such as raising the blood glucose target levels, may not be under their control. Parents also report substantial anxiety and fear of hypoglycemia, and they too may engage in behaviors that serve to avoid hypoglycemic events.²⁸

School-age children with diabetes can begin to assume some of the daily diabetes management tasks, such as insulin injections and blood glucose testing. However, they will still need significant assistance from their families for management decisions. It is important to encourage school-age children to attend school regularly and to participate in school activities and sports to facilitate the development of normal peer relationships. Children with diabetes

often feel that they are different from their peers because of the diabetes and may be at risk for difficulties with social competence.²⁹

Adolescent

Adolescence is a period of rapid biological change accompanied by increasing physical, cognitive, and emotional maturity. Adolescents are struggling to find their own identity separate from their families. If they have difficulty with identity formation, Erikson³⁰ describes it as role confusion. Many of the diabetes care-related tasks can interfere with the adolescent's drive for independence and peer acceptance. Peer pressure may generate strong conflicts. In this age group, there is a mighty struggle for independence from parents and other adults that is often manifested as poorer adherence to the diabetes regimen. Cognitively, adolescents are beginning to attain the skill of formal operations.⁸ Formal operations allow adolescents to "think about their own thinking," transfer information from one situation to another, deal efficiently with complex problems, plan realistically for the future, and conceptualize more abstract ideas. Perhaps because adolescents often manifest more difficulties in diabetes management and more overt psychosocial problems than younger children, the great majority of psychosocial and behavioral literature deals with adolescents.

Hormonal changes trigger the onset of puberty and the development of secondary sexual characteristics, ultimately resulting in the attainment of adult stature and proportion. During this period, adolescents are narcissistic, being preoccupied with their bodies and the changes occurring to them. Second, teens evolve from concrete thinkers into abstract thinkers, making understanding of the relationship of self-care to outcomes difficult. The period is also marked by feelings of ambivalence, impulsiveness, and mood swings, associated with the struggle with separation from parents and the need to be accepted by peers. Finally, adolescents engage in experimentation and risk-taking behaviors which may adversely affect self-care and clinical outcomes as well.

Metabolic control tends to deteriorate in adolescence as a result of several factors: the natural decrease to zero of the production of insulin by the pancreas; the hormonal changes of adolescence, which are associated with insulin resistance and the corresponding need for very large doses of insulin;³¹ and adolescent rebellion, which is associated with poorer adherence to the treatment regimen.³² To further complicate matters, adolescents who are most successful in lowering plasma glucose levels are at the greatest risk for severe hypoglycemic events.²

For the most part, it is accepted that diabetes is a risk factor for adolescent psychiatric disorder.³³ Approximately three times more adolescents with diabetes have psychiatric disorders than their age-mates, with rates as high as 33%. This increased morbidity is primarily associated with the incidence of major depression (approximately 27.5%)³⁴ and generalized anxiety disorder (18.4%), rather than psychiatric behavioral disorders.³³ Furthermore, a substantial number of adolescents with diabetes consider suicide after the onset of the disease.³⁵ The rate of suicidal ideation has been found to be higher than would be expected (26.4%), but in contrast, the number of suicide attempts was only 4.4%, which is a rate comparable to the general population of adolescents.³⁶ In addition, adolescents who have recurrent diabetic ketoacidosis may be more likely to have psychiatric disorders, especially anxiety and depression, than those without recurrent hospitalization.³⁷ These studies are important because not only is psychiatric illness a serious com-

plication of diabetes, it may be associated with poorer metabolic control.

Eating disorders have also been associated with diabetes in adolescents. This topic has been studied for nearly 20 years with mixed findings. Several studies have suggested that adolescents with diabetes are at no higher risk for eating disorders than their peers without diabetes,^{38,39} whereas other studies have found rates of both anorexia and bulimia to be higher in youths with T1DM, and have described a specific type of eating disorder seen in these patients, insulin omission to control weight.⁴⁰ Youths, especially girls, with such eating disorders are more likely to have other psychiatric morbidity, as well as poorer metabolic control of diabetes⁴¹ and recurrent hospitalizations.⁴²

How individuals cope with the burdens of a chronic condition has an important impact on the effectiveness of therapy. Coping with the demands of self-management can be a formidable task. These demands include both the physical demands of management as well as the emotional and social demands of adaptation. A variety of studies have demonstrated that the period of adolescence is often associated with neglect of self-monitoring, dietary recommendations, and pharmacologic treatments. Such neglect in self-management is usually not associated with a deficit in knowledge; rather the cognitive and developmental characteristics of adolescence make appropriate decision making more complex. Thus adolescents are at high risk for poorer clinical outcomes, hospitalization, and eventually, the development of long-term complications.^{14,43}

While a smaller percentage of adolescents with diabetes manifest significant psychiatric problems, many have difficulty in psychosocial adjustment. The presence of diabetes in adolescence may hinder normal adolescent development by limiting the development of independence. One recent study⁴⁴ examined the personal meaning and perceived impact of diabetes on 54 adolescents and found that youths felt that diabetes controlled or limited their freedom and independence. Girls have been found to report more symptoms of anxiety and depression related to these restrictions and to be in worse metabolic control than boys.⁴⁵

Because difficulties in regimen adherence are so common in adolescents,³² and poorer regimen adherence is associated with poorer metabolic control,⁴⁶ there have been a number of studies that have examined factors associated with adherence. Such factors may be internal, such as coping behaviors or styles,⁴⁷ gender,^{45,48} age,^{32,49} and motivations,⁵⁰ or external, such as the supportiveness of the family⁵¹ and the health care system.⁵² Adolescents who frequently neglect self-management have less motivation and less support and believe that nonadherence is an issue of personal freedom.⁵³

Adolescence is also a period of intense experimentation with risky behaviors. Interestingly, although youths with diabetes frequently experiment with diabetes mismanagement through nonadherence, the rates at which they report other risky behaviors, such as alcohol use, smoking cigarettes, drug use, and unprotected intercourse, are lower than the general population of adolescents.⁵⁴ These rates are still substantial, however, and many of these behaviors can interfere with diabetes self-management as well. Furthermore, while girls are more likely to participate in diabetes mismanagement, boys are more likely to engage in risky behaviors.⁴⁸

Although adolescents are struggling to define their own identity apart from the family, the family has continued and profound effects on the adolescent with diabetes. A number of studies provide support for the association between family cohesion and better metabolic control in adolescents,⁵⁵ but there is some evidence that this relationship may be attenuated by disease duration.⁵⁵

Other researchers have also shown that adolescents whose parents maintain some guidance and control in the management of diabetes have better metabolic control.^{17,56} Thus, continuing to involve parents appropriately, with shared management, is associated with improved control. The challenge is to find the degree of parental involvement that is comfortable for all involved, without risking poorer control from overinvolvement or underinvolvement.⁵⁷ Such involvement in diabetes management in this developmental stage can affect parent-adolescent relationships. Parent-child conflict has been associated with poorer diabetes outcomes in several studies.^{58,59}

Transition to Young Adulthood

It is only recently that the issues related to the long-term outcomes of youths who have chronic conditions have received attention in the literature, much of it concerned with the differences in approaches between pediatric care and adult care.⁶⁰ Bussing and Aro surveyed adolescents in a school at age 16 and again at age 22 and compared individuals with chronic conditions to those without chronic conditions, to determine the effect of the chronic condition on a variety of functional outcomes.⁶¹ They found that adolescents with chronic health conditions attained levels of well-being, education, and marriage or dating as young adults similar to their peers without chronic conditions. Their findings also suggest, however, that males with a chronic condition may be at higher risk for depression than females or those without chronic conditions. Wysocki and colleagues studied 81 young adults with diabetes and found higher rates of psychopathology compared to others, and that poorer metabolic control and poorer adjustment to diabetes in adolescence are associated with poorer status in early adulthood.⁶² On the other hand, Pless and colleagues retrospectively surveyed 431 young adults (aged 18–34 years) and found that efforts to achieve better metabolic control during childhood, whether successful or not, were not associated with psychosocial problems later in life.⁶³ In one of the few longitudinal studies of youths with chronic conditions, Jacobson and colleagues⁶⁴ found that DM patients had lower perceived competence, self-worth, and sociability than young adults without chronic illness. All of these studies, however, were conducted prior to the release of the findings of the Diabetes Control and Complications Trial (DCCT) and the recommendations for intensive treatment for all youths. Since improved metabolic control is achieved earlier as a result of intensive therapy, it may be that such regimens will be associated with improved status over time, but this assumption has not been evaluated.

INTERVENTIONS AND IMPLICATIONS FOR TREATMENT

Team Management

Given the complexity of diabetes management, children and adolescents with T1DM should be routinely cared for at a diabetes center that employs a multidisciplinary team of practitioners who are knowledgeable about and experienced in the management of young patients.⁶⁵ Such teams should ideally consist of pediatric endocrinologists, diabetes nurse specialists or practitioners, dietitians, social workers or psychologists, and referral resources for eye, renal, neurologic, and other problems. Such teams need to project a positive, upbeat approach to treatment, communicate well among themselves, and be self-critical of their own performance.

Databases that track overall clinic performance with respect to important outcomes can be very useful.

Psychosocial Interventions

There have been a number of studies on the effects of psychosocial interventions for children and adolescents with diabetes. Reports on psychosocial interventions include those that focused on coping skills training, stress management and relaxation, and social support in groups or camps.

A series of studies have been conducted using coping skills training for children and adolescents with diabetes. Coping skills training is designed to increase competence and mastery by retraining inappropriate or nonconstructive coping styles and patterns of behavior into more constructive behaviors. Coping skills training for youths with diabetes is based on the hypothesis that improving coping skills will improve the ability of youths to cope with the problems faced on a day-to-day basis in managing diabetes.

In an experimental study that combined both instruction in blood glucose management and coping skills training called Stress Management Training in Adolescents, Boardman and associates found that while diabetes-specific stress was decreased in the experimental group, there were no differences in metabolic control, measured by HbA_{1c}, coping styles, self-efficacy, life events, or adherence over 9 months. In contrast, Grey and colleagues⁶⁷ reported on the results of a larger randomized clinical trial, with a sufficient sample to achieve statistical power, to determine both metabolic and psychosocial effects of coping skills training. These studies focused on adolescents initiating intensive insulin therapy after the results of the DCCT were released.² In their study of 77 youths they found significant improvements in metabolic control, general self-efficacy, and quality of life as compared to the control group over 12 months of follow-up.⁶⁷

Two studies were found that used meditation and other forms of stress reduction as a method to improve diabetes care and outcomes. Since stress has been found to be associated with alterations in metabolic control, it is hypothesized that such interventions will assist those with diabetes to have better metabolic control. Mendez and Belendez⁶⁸ conducted a quasi-experimental study of stress management in 37 adolescents and compared this program to routine medical care. The program consisted of 12 sessions that included review, information, and practicalities of diabetes management, with a focus on stress and coping with stress, including problem solving. Results showed posttest improvements in diabetes information, adherence, daily hassles, social responses, skills, frequency of testing, and errors in blood glucose testing, as measured by observation, and negative family support. There were no effects on self-reported dietary and physical exercise behavior or metabolic control. When retested at 13 months after the intervention, knowledge, barriers to adherence, hassles, and social interaction remained better in the stress management group.

Over the years, a number of studies have suggested that social support is associated with improved adherence and metabolic control in adolescents with diabetes, but despite the understanding that social support is important, there have been relatively few investigations of socially supportive interventions.⁵² These interventions differ from group approaches used to teach coping skills and other approaches in that the goal is to improve the supportiveness of the environment rather than to attain specific skills. Interventions that focus on the family as the unit of social support are discussed below under family interventions.

Dr. Barbara Anderson and colleagues⁶⁹ examined the effectiveness of a peer group intervention for young adolescents to attempt to prevent the usual decline in metabolic control associated with adolescence. They hypothesized that providing peer support and education in making adjustments in the diabetes regimen according to self-monitored blood glucose results would prevent this decline. In this intervention, small groups of adolescents met at each of their clinic visits. Emphasis was placed on the use of blood glucose data and peer support to improve control. Results indicated that metabolic control was significantly better in the experimental group, who reported more adjustments for exercise, diet, and insulin dose based on blood glucose testing than did those who received routine follow-up care.

Others are interested in social support provided over the telephone or by adult mentors for younger youths. Daley⁷⁰ paired adults with T1DM with adolescents with newly diagnosed diabetes to improve adolescents' adjustment to diabetes. The sample for this study differs from many intervention studies, in that it is approximately 44% minority (Hispanic and African-American). The 54 subjects ranged in age from 12–16 years, and the sponsor intervention was provided for 10 months. Results indicated that for the most part, there were no differences (metabolic control, behavior, adjustment, anxiety) between the sponsorship group and the control group, but subjects in the sponsorship group reported an increase in social acceptance and romantic appeal. Furthermore, in qualitative interviews, subjects in the experimental group reported that the sponsors provided an important source of previously unavailable support.

In summary, there have been a number of psychosocial approaches studied for children and adolescents with diabetes, but the majority have been conducted with adolescents. Little attention has been paid to younger children and to the families and extended families of these children. Many of these reports are not rigorous experimental designs, but case control studies or one-group pretest-posttest preexperimental designs. Nonetheless, where adequate controlled studies have been done, interventions such as coping skills training and peer support have been demonstrated to lead to improved adjustment or quality of life as well as improved metabolic control.

Family interventions are those in which the target of the intervention is the family members of a child or adolescent with diabetes rather than the index child. Reviews of the literature on family aspects of chronic illness reinforce the view that while there have been methodological problems in studying families of individuals with chronic illness, families have an important influence on children and adolescents with diabetes.⁷¹

Studies of family intervention include those whose intervention was targeted on family members, primarily parents, and did not focus on outcomes in children, adolescents, or parents alone. Satin and associates⁷² conducted an experimental study of a multifamily group intervention of support and guidance, and a multifamily group intervention plus parent simulation of diabetes, and compared outcomes with a control group of adolescents and families who received routine care. A total of 32 families participated and were randomly assigned to the three groups. The interventions consisted of six weekly sessions that included adolescents and their parents, in which guidance and support were provided, using principles of group therapy. For the group who received the multifamily intervention plus simulation, the parents simulated having diabetes and doing all of the self-care for 1 week. Controls received routine care. Results indicated that the group who received the

multifamily intervention with simulation had the best improvement in metabolic control. Parents in both intervention groups had more positive perceptions of teens with diabetes, but no differences were found on estimates of self-care or family environment.

Wysocki and colleagues^{73,74} conducted experimental studies that compared the effectiveness of Behavioral Family Systems Therapy with that of education and support groups for families of adolescents in reducing parent-adolescent conflict in diabetes management. This intervention focused on families with pretest scores demonstrating at least moderate general or diabetes-specific family conflict. Behavioral Family Systems Therapy targets parent-adolescent conflict by focusing on family problem solving and communication skills, the degree to which family members hold extreme beliefs about one another's behavior, and the extent of family structural or systemic anomalies. The experimental treatment consisted of 10 sessions with parents and adolescents that emphasized problem solving for conflict resolution, communication skills training for parent-adolescent communications, cognitive restructuring for family members' beliefs and attributions, and functional or structural family therapy to target maladaptive characteristics of family functioning. A total of 119 families with adolescents with diabetes participated in these studies. Using scales developed and validated for this study, results demonstrated that the Behavioral Family Systems Therapy showed more improvement in parent-adolescent relationships, diabetes-specific family conflicts, treatment adherence, metabolic control (in boys and younger girls only), and treatment evaluation as compared to education and support groups. By 6 months, the improvements in parent-adolescent relationships were maintained, but those related to adherence or metabolic control were not.

As parents and children negotiate responsibilities in diabetes management, and as these responsibilities change over time, it is likely that parent-adolescent conflict will develop. Anderson and colleagues⁷⁵ developed an office-based intervention aimed at maintaining parent-adolescent teamwork in diabetes management tasks without increasing diabetes-related family conflict. In a study of 85 adolescent patients and their parents, they found that the brief intervention carried out in quarterly office visits for 12 months led to no decrease in parental involvement in insulin administration and blood glucose testing, with significantly less family conflict as compared to usual care. Over a 24-month follow-up period, average levels of glycosylated hemoglobin did not differ between the groups, but more teens in the teamwork group had improved control than in the comparison group.

SUMMARY

Clearly, type 1 diabetes diagnosed in childhood has a profound effect on children and their families. Diabetes requires constant vigilance to maintain good metabolic control without increasing the risk of severe hypoglycemia. Both parents and children struggle with this awesome responsibility, and they may need special interventions to assist in not only maintaining good metabolic control, but also improving their quality of life.

Diabetic Ketoacidosis

Elizabeth Delionback Ennis

Robert A. Kreisberg

Diabetic ketoacidosis (DKA) is an important and serious complication of decompensated diabetes mellitus. Each year there are approximately 798,000 individuals with newly diagnosed diabetes mellitus (DM).¹ By 1998, there were an estimated 15.7 million persons in the U.S. (5.9% of the total population) with diabetes mellitus.¹

In 1994, the most recent year for which data are available, there were 113,000 hospital discharges in which DKA was listed and 89,000 in which it was the primary diagnosis.¹ Although impressive, these data underestimate the true incidence of DKA since mild diabetic ketoacidosis is often treated in a physician's office or an emergency department. In 1997, \$1.324 billion out of a total of \$44.138 billion spent on diabetes was expended for treatment of acute metabolic conditions (~3% of the total).¹ Based on the reported 1994 prevalence of DKA, this leads to a calculated cost of \$12,000–\$15,000 per episode.¹

DKA is the presenting manifestation of type 1 diabetes mellitus in only 20–25% of cases, and most cases of DKA do not occur in individuals with new-onset diabetes mellitus.^{2,3} Eighty percent of DKA episodes occur in patients who are known to have diabetes mellitus. Since the majority of the episodes of DKA occur in patients with known diabetes mellitus and 20% of patients with DKA have multiple annual episodes, better patient education is needed.

DKA occurs with equal frequency in men and women; however, it does not occur with equal frequency in all races.¹ African-Americans have an excess DKA burden and data from 1980–1994 show that African-Americans had 2.3 times more hospital discharges for DKA than whites (15.7 episodes versus 6.8 episodes per 1000 diabetic population).¹ Additionally, the rate of DKA increased in African-Americans from 1980–1994, while during the same time it decreased in whites.¹

Overall, the DKA death rate did not change from 1980–1994.¹ Each year there are approximately 1800 deaths in which DKA is the primary diagnosis.¹ There are an additional ~2800 deaths yearly in which DKA is a contributing cause of death.¹ From 1980–1994 the age-adjusted DKA death rate decreased 34%.¹ The highest DKA death rates are in persons >75 years of age, likely due to their comorbid medical conditions, and in persons <45 years of age.¹ African-American men have the highest DKA death rates, followed by African-American women and whites.¹ DKA mortality data are not available for many other ethnic groups such as Native Americans and Hispanics in whom diabetes is a prevalent condition.

Ketoacidosis is generally thought to be a problem of young diabetics; however, the average age of patients with ketoacidosis is 43 years and 50–85% of the episodes of DKA occur in adults.^{3,4} Since these data were collected when the terms juvenile-onset and adult-onset diabetes were still being used, the results cannot be directly extended to type 1 diabetes mellitus (T1DM) and type 2 diabetes mellitus (T2DM). Some older patients have T1DM and are predisposed to the development of DKA just as are younger patients. Many patients with DKA probably have T2DM since 19% of the patients in one series were obese.³

Although the entities of DKA and hyperglycemic hyperosmolar syndrome (HHS) are often discussed as separate problems, many authors believe they represent states of decompensated diabetes that differ only by the magnitude of dehydration and the severity of acidosis. Careful review of large numbers of patients with decompensated diabetes mellitus suggests a continuum of decompensation with DKA at one extreme and HHS at the other.⁵ Among patients with decompensated diabetes, 22% have DKA, 45% have HHS, and 33% have features of both.⁶

DKA may not be obvious at admission; in one series 20% of patients were not initially recognized to have ketoacidosis and were admitted to the hospital for a primary diagnosis other than diabetes mellitus.³

PATHOGENESIS OF DIABETIC KETOACIDOSIS

Although DKA is a complex metabolic disturbance of glucose, fat, and protein metabolism, the signs and symptoms are primarily due to abnormalities in the metabolism of carbohydrate and fat. The biochemistry of ketogenesis, which is critical in DKA, is discussed in detail in Chap. 2.

Hyperglycemia and consequently hyperosmolality occur as a result of overproduction of glucose by the liver and underutilization of glucose by peripheral tissues. When the blood glucose concentration exceeds the threshold for renal tubular reabsorption of glucose, glucosuria occurs and, as a result of the osmotic diuresis, water is lost in excess of electrolyte. Glomerular filtration is initially increased as water moves from the intracellular to the extracellular compartment due to the increase in extracellular osmolality. With the development of marked hypovolemia, glomerular filtration and renal glucose losses diminish, resulting in more severe hyperglycemia.

Because of the tight metabolic coupling of hepatic gluconeogenesis to ketogenesis, ketone body production is activated in DKA; its magnitude usually parallels that of glucose production. Ketoacidosis is primarily due to the overproduction of ketoacids by the liver, although underutilization of ketones makes a minor contribution to the ketonemia. The increase in ketoacid production causes the loss of bicarbonate and other body buffers, resulting in the development of metabolic acidosis.

DKA develops as a consequence of a deficiency of insulin and an excess of the glucose counterregulatory hormones catecholamines, cortisol, glucagon, and growth hormone.⁷⁻⁹ The insulin deficiency may be relative rather than absolute. Insulin concentrations in patients with DKA are $\sim 10 \mu\text{U/mL}$,⁹ values that are clearly normal under basal conditions in a euglycemic individual, but are inappropriately low for the hyperglycemia that exists in patients with ketoacidosis. Glucose counterregulatory hormone concentrations are increased in DKA, as a result of coexistent physical and emotional stress or illness,⁹ or simply as a consequence of insulin deficiency.⁸ The concentrations of some of these hormones increase when insulin therapy is withdrawn under controlled experimental conditions that minimize stress and hypovolemia.^{8,10} The administration of specific counterregulatory hormones to patients with T1DM who continue to receive intravenous insulin at rates that maintain basal insulin concentrations increases glucose and ketone body concentrations.⁹ The development of DKA in patients who continue to take their insulin further emphasizes that the balance between insulin and the counterregulatory hormones is very important in the pathogenesis of ketoacidosis. The predisposition of the patient with diabetes to ketoacidosis is further amplified by the accentuated release of the glucose counterregulatory hormones that occurs in poorly controlled diabetes. The poorly controlled diabetic develops higher concentrations of certain counterregulatory hormones for any given level of stress than does the nondiabetic.^{11,12} In addition, the biologic response to a given concentration or dose of a glucose counterregulatory hormone is exaggerated in DKA.¹³ Studies conducted in animals and humans for the purpose of understanding stress hyperglycemia demonstrate that the glucose counterregulatory hormones interact in a synergistic, rather than additive, manner (see Chap. 9).^{14,15}

Glucagon is of particular importance in the development of DKA, because it influences both gluconeogenesis and ketogenesis (see Chap. 7). At physiologic concentrations, glucagon does not inhibit glucose utilization by peripheral tissues nor does it increase fat mobilization. When there is an absolute or relative deficiency of insulin, glucagon directly stimulates gluconeogenesis and ketogenesis. Glucagon secretion is increased in DKA and the magnitude of ketone body production directly correlates with the plasma glucagon concentration.⁸ A deficiency of insulin and/or an excess of catecholamines, cortisol, and growth hormone augments hepatic

glucose production, inhibits peripheral glucose utilization, increases fat mobilization, and stimulates ketogenesis.¹⁶⁻²² Free fatty acids (FFAs) provide the substrate necessary to support glucagon-stimulated hepatic ketogenesis. Glucagon can directly increase ketone body production in the absence of increased FFA release from adipose tissue by activating lipolysis of hepatic triglyceride. However, sustained production of ketone bodies requires an adequate supply of substrate FFAs.²³ The central role of glucagon in the development of ketoacidosis is emphasized by the attenuation that occurs in the rates of gluconeogenesis and ketogenesis when glucagon secretion is inhibited with somatostatin.^{24,25} When insulin is withdrawn from diabetic patients, the major hormonal factors leading to DKA are probably insulin deficiency and glucagon excess.

The presence of increased concentrations of cortisol, epinephrine, growth hormone, and norepinephrine accentuates the impairment in peripheral glucose utilization and enhances lipolysis produced by insulin deficiency. In this way, the glucose counterregulatory hormones directly or indirectly increase ketone body production. In addition, epinephrine and cortisol are capable of increasing hepatic glucose production, through both glycogenolysis and gluconeogenesis.

The withdrawal of insulin from well-controlled patients with T1DM results in a prompt increase in hepatic glucose and ketone production.⁸ Glucose utilization increases transiently, probably due to enhanced glucose utilization by non-insulin-dependent tissues, but glucose clearance is markedly reduced.⁸ When insulin is readministered to these patients, glucose and ketone production decrease promptly, as do the plasma glucose and ketone body concentrations. However, these are controlled conditions in which hypovolemia and other stress factors are not present. Consequently, the roles of cortisol, epinephrine, and growth hormone in the development of DKA are minimized.

The withdrawal of insulin from previously well-controlled diabetics leads to progressive increases in the concentrations of epinephrine and glucagon.⁸ These hormones are considerably more important in the development of ketoacidosis under everyday circumstances when illness, physical and emotional stress, and hypovolemia are coexistent factors. Although it is likely that the elevated concentrations of glucose counterregulatory hormones may themselves play an important role in the metabolic decompensation of DKA, their elevation may be due solely to insulin withdrawal. Whatever the role of the glucose counterregulatory hormones, they are clearly capable of further intensifying the metabolic defects that exist in DKA. Stress leading to the release of the glucose counterregulatory hormones can precipitate DKA in the presence of the usual insulin dose, whereas omission of insulin and its ensuing deficiency can result in the release of glucose counterregulatory hormones that further aggravate the metabolic effects of insulin deficiency.

TABLE 34-1. Effects of Insulin and Insulin Counterregulatory Hormones

	Gluconeogenesis Liver	Ketogenesis Liver	Glucose Utilization Muscle	Lipolysis Adipose Tissue
Insulin	↓	↓	↑	↓
Glucagon	↑	↑	→	→
Epinephrine	↑	↑	↓	↑
Cortisol	↑	↑	↓	↑
Growth hormone	→	↑	↓	↑

Glucose counterregulatory hormones decrease tissue responsiveness to insulin beyond the binding of insulin to its receptor (i.e., postreceptor or postbinding defect). Thus normal basal concentrations of insulin are less effective when there are increased concentrations of the glucose counterregulatory hormones. The biologic effects of these hormones are summarized in Table 34-1.

Recently, the possibility that prostaglandins (PGI_2 and PGE_2) may play a role in DKA was considered because their production is increased in experimental models of insulin deficiency.²⁶⁻²⁸ In particular, it has been suggested that PGI_2 may contribute to the nausea, vomiting, abdominal pain, and "warm shock" commonly seen in patients with DKA.²⁶

PRECIPITATING FACTORS

Intercurrent illness and discontinuation of insulin represent the two most readily identifiable factors that lead to the development of DKA.^{4,29,30} Coexistent medical illness is the most common factor, accounting for 50–60% of the causes of DKA.^{4,29,30} Infection is a common precipitating factor in patients with DKA. The inadvertent or unsuspected interruption of insulin administration due to pump malfunction in patients on continuous subcutaneous insulin infusion (CSII) is relatively common in some centers.^{31,32} For example, in one study approximately 30% of patients treated with CSII developed ketoacidosis; half of the episodes were due to unnoticed interruption of insulin delivery, whereas the other half were associated with infection.³² Fasting of moderate duration may potentiate the ketosis that occurs with insulin deficiency in T1DM patients while reducing the degree of hyperglycemia.³³

In approximately 20–30% of patients with DKA, no precipitating factor can be found. This suggests that emotional stress may contribute to the development of DKA in certain patients.³⁴ Although recent studies have not supported the importance of psychological stress as a precipitating factor,³⁵ the stress models used in these studies do not duplicate the type of personal stress that individual patients may encounter in daily living.³⁶ A criticism of these studies is that the attempt to evaluate whether stress significantly alters diabetic control was conducted in well-controlled diabetics. It would be far more useful to study the effects of stress in patients whose diabetes is poorly controlled.

Recently, insulin omission as a feature of eating disorders was highlighted in a study of 341 women with T1DM who were 13–60 years of age.³⁷ Thirty-one percent of the women reported intentionally omitting insulin. This practice was most common among women aged 15–30 years (40.2%). Thirty percent of women aged 31–45 years and 19.7% of women aged 46–60 years reported insulin omission.³⁷ Sixteen percent of women aged 15–30 years, 4.3% of women aged 31–45 years, and 6.1% of women aged 46–60 years reported routine insulin omission.³⁷ The women who omitted insulin had significantly more eating attitude and eating behavior problems (fear that good glycemic control would lead to weight gain or feeling bloated), higher hemoglobin A_{1c} values, more diabetes-related hospitalizations, increased emergency room visits, and a higher rate of neuropathy and retinopathy.³⁷ Omission of insulin is used by these girls and women to control their weight. A significant number of women reported omitting insulin to the point that they developed ketonuria. Although contrary to many studies, eating disorders have been shown to be twice as common in adolescent girls with T1DM than in those without diabetes.³⁸

In urban African-Americans, poor compliance with regimens and substance abuse have been identified as important precipitating causes of diabetic decompensation.³⁹ In a prospective study of 144 consecutive DKA patients and 23 patients in a large inner-city hospital, poor compliance with therapy was found to be the major precipitating factor for DKA found in 49% of patients.³⁹ Thirty-five percent of the DKA patients had confounding alcohol abuse and 13% had cocaine abuse of which may lead to poor compliance with medical regimens compound economic stresses.³⁹ In another study of DKA patients, cocaine was associated with frequent omission of insulin and absence of a precipitating cause of DKA other than use.⁴⁰ Cocaine is associated with recidivism and recurrent episodes of DKA.⁴⁰ The mechanisms by which cocaine, in particular, precipitate DKA are numerous and include effects on glucose counterregulatory hormones in addition to the direct central nervous system effects of the drug.⁴⁰

An atypical form of ketoacidosis has been described in obese African-Americans, but has recently also been seen in other races and ethnic groups.⁴¹⁻⁴³ There is no history of preexisting diabetes mellitus and no obvious precipitating event. Their C-peptide levels are normal and anti-islet cell antibodies are negative. The cause of the absence of autoimmune markers and its lack of association with specific HLA alleles and increased insulin requirement appears to be a form of T2DM. This is supported by the high prevalence of coexistent hypertension. Following control of DKA, patients can often be initially managed with diet and low-dose sulfonylurea agents.⁴⁵

In menstruating women, menstruation is associated with an increased incidence of DKA. Of 200 women studied, 76 reported changes in diabetic control related to menstruation.⁴⁶ Fifty women reported deterioration of glycemic control during menstruation and 23 reported improved control and increased insulin requirements.⁴⁶ DKA has also been associated with sauna use, the ingestion of "ecstasy" followed by prolonged exercise, gestational diabetes, the use of glucocorticoids in a patient with gestational diabetes, and in glucagonoma.⁴⁷⁻⁵⁰

DIAGNOSIS

Traditionally, DKA is defined by a glucose level ≥ 300 mg/dL, $\text{HCO}_3^- \leq 18$ mEq/L, and a pH ≤ 7.30 . A pH less than 7.35 in a patient with ketonemia and a glucose concentration greater than 300 mg/dL identify mild DKA. Because acute hyperventilation lowers the serum bicarbonate by as much as 5 mEq/L,⁵¹ the presence of a bicarbonate less than 18–19 mEq/L in a patient with appropriate hyperglycemia should also suggest this diagnosis. Blood glucose concentration used as a criterion for DKA is difficult to define because there are patients with blood glucose concentrations above 300 mg/dL who have no evidence of DKA and a substantial number of patients with established DKA whose blood glucose concentrations are less than 300 mg/dL.⁵² This emphasizes the variable expression of diabetic decompensation. Hyperkalemia need not be striking, and approximately 15% of patients with DKA have glucose concentrations of less than 350 mg/dL. Low glucose concentrations may be seen in settings where there may be inhibition of gluconeogenesis, such as with the use of ethanol, and in settings where glucose utilization is not completely insulin dependent, such as in women who are pregnant in whom the fetal-placental unit uses glucose in the absence of insulin. For

TABLE 34-2. Calculations

Anion gap = $[Na^+ - (Cl^- + HCO_3^-)]$	Normal = 8–14 mEq/L
	Average = 5–12 mEq/L
Δ Gap = [patient gap – 12]	
Primary gap acidosis = Δ anion gap/ $HCO_3^- \geq 0.8$	
Primary nongap acidosis = Δ anion gap/ $HCO_3^- \leq 0.4$	
$Na^+_{corr} = SNa^+ + 1.5 [(glucose - 150)/100]$	

may also be an important factor in the patient with DKA and mild hyperglycemia. Fasting in the setting of insulin deficiency is associated with less severe hyperglycemia and more severe ketoacidosis.³³ It is important to realize that despite relative “euglycemia,” patients may be critically ill as a result of severe metabolic acidosis.

The pH of a patient with DKA depends on the degree of respiratory compensation as well as the presence of coexistent acid-base disturbances. The metabolic acidosis that occurs in DKA is one in which there is an increase in the anion gap. The anion gap is calculated by subtracting the sum of the chloride and bicarbonate concentrations from the “uncorrected” sodium concentration $[Na^+ - (Cl^- + HCO_3^-)]$ ⁵³ (Table 34-2). This difference represents the unmeasured anions that are present in plasma, primarily albumin and phosphate. The normal range is from 8–14 mEq/L; a value of 12 mEq/L is usually used to determine whether the anion gap is increased. In DKA, the increase in the anion gap is usually equal to the reduction in the bicarbonate concentration. However, many patients with DKA may deviate from this pattern and demonstrate varying degrees of anion-gap and hyperchloremic metabolic acidosis.⁵⁴ Wide variability in the type of metabolic acidosis will be detected if the increase in the anion gap is compared to the reduction in bicarbonate concentration (assuming that a normal baseline bicarbonate level existed before ketoacidosis developed) in DKA patients. At presentation ~46% of patients with DKA have a predominant anion-gap acidosis, 43% have a mixed anion-gap and hyperchloremic acidosis, and 11% have a predominantly hyperchloremic metabolic acidosis⁵⁴ (Table 34-3). Thus, in contrast to traditional thinking, at presentation approximately 55% of the patients have a hyperchloremic metabolic acidosis or a component of hyperchloremia.⁵⁴ The variable degree of hyperchloremia in DKA correlates with the magnitude of the hypovolemia that exists in the patient.⁵⁴ Patients with severe hypovolemia develop the typical reciprocal change in the anion gap and the bicarbonate concentration, due to retention of both the hydrogen ion and the ketoacid anion. In contrast, those patients who can maintain adequate volume and glomerular filtration while developing DKA excrete the ketoacid

TABLE 34-3. Acid-Base Disturbances in DKA at Admission and During Therapy

anions in the urine while reabsorbing chloride, which leads to hyperchloremia.

The coexistence of other acid-base disturbances—such as metabolic alkalosis from nausea and vomiting or diuretic use, respiratory alkalosis from fever, infection, sepsis, or pneumonia, and hyperchloremic metabolic acidosis from diarrhea—can confound the diagnosis of DKA.⁵¹

Thus patients with coexistent medical problems may not have simple acid-base disturbances. For example, a hypochloremic, hypokalemic metabolic alkalosis induced by diuretic use may produce offsetting changes in systemic pH in a patient with DKA, which could erroneously suggest that the acidosis is mild when it is severe. An increase in the anion gap that is greater than the calculated reduction in the bicarbonate concentration should suggest coexistent metabolic alkalosis or respiratory acidosis in a patient with hypochloremia. The magnitude of the coexistent alkalosis may be even greater than that of the acidosis, so that the pH of the patient will be alkalemic (“diabetic ketoalkalosis”).⁵⁵ If patients become alkalemic during recovery, a coexistent metabolic alkalosis should be considered. The presence of a chronic respiratory acidosis would minimize changes in bicarbonate concentrations while intensifying the acidemia.

In an uncomplicated patient with DKA, the respiratory response may be capable of reducing the PCO_2 to 10 mm Hg, and the bicarbonate concentration may be as low as 5 mEq/L. More severe reductions in the bicarbonate concentration or less than optimum reduction in the PCO_2 indicates the coexistence of other acid-base disturbances.

The osmolal gap (difference between the measured and calculated serum osmolality) may be increased in DKA. This value is usually <10 mOsm/L. When increased, it suggests the presence of low-molecular-weight alcohols, which also cause a “gap acidosis.” The increase appears to be due in part to acetone and amino acids and in part to hemoconcentration.⁵⁶

LABORATORY AND WATER ABNORMALITIES

Substantial deficits of sodium, potassium, magnesium, phosphorus, and water can develop in patients with DKA (Table 34-4). However, despite these deficits most patients have normal or elevated plasma concentrations of potassium, magnesium, and phosphorus at the time of presentation (Tables 34-5 and 34-6).^{57,58} The presence of normal or increased electrolyte concentrations should not be interpreted to mean that body stores of these elements are normal or increased. The deficit in potassium is the most important;

recognition and treatment of potassium deficiency is of major therapeutic importance.

The deficit of potassium in patients with DKA is 3–5 mEq/kg. During the course of therapy, the serum potassium concentration rapidly decreases, reaching a nadir at approximately 4–12 hours after beginning insulin therapy.⁵⁸ The deficit of potassium will become obvious during the course of therapy, particularly if potassium is not administered in adequate amounts. The hyperkalemia that exists in patients with DKA is usually attributed to a shift of hydrogen ion from the extracellular to the intracellular compartment and of potassium from the intracellular to the extracellular compartment. Other factors have been identified that may be more important determinants of the potassium concentration in DKA.⁵⁹ The potassium concentration in patients with DKA correlates best with the severity and magnitude of the existing ketoacidosis and hyperglycemia.⁵⁹ The administration of glucose to produce hyperglycemia in normal animals stimulates insulin release and the movement of potassium into the intracellular compartment. When insulin release is blocked in the presence of hyperglycemia, such as with the infusion of somatostatin to normal subjects, the serum potassium increases.⁶⁰ Thus, insulin deficiency is a major cause of the hyperkalemia that develops in patients with DKA. In normal animals, ketoacid infusion increases the secretion of insulin, elevates portal vein insulin concentrations, stimulates hepatic uptake of potassium, and lowers serum potassium concentrations.⁶¹ In

contrast, the infusion of mineral acid stimulates the release of glucagon but not of insulin, increases hepatic potassium release and causes hyperkalemia. Lastly, when volume contraction becomes sufficiently severe so as to reduce the glomerular filtration rate, decreased excretion of both potassium and glucose in the urine accentuates the hyperkalemia. Thus the tendency for the serum potassium concentration to decrease rapidly during therapy may be a reflection of the direct action of insulin on cellular potassium uptake, alterations in systemic pH, a reduction in the serum glucose concentration and associated hyperosmolality, and enhanced renal potassium excretion.

A deficit of phosphorus occurs during the development of DKA and may reach 1.0–1.5 mmol/kg of body weight.⁵⁷ However, since total body phosphorus stores are 6000–8000 mmol, this represents a mild degree of phosphorus deficiency. The hyperphosphatemia that exists at diagnosis of DKA is attributed to the effect of metabolic acidosis on cellular function and the release of phosphate.

While hypophosphatemia often develops during the course of therapy, adverse effects are rare.^{62–64} Serious complications of hypophosphatemia are encountered only when the serum phosphate concentration falls to less than 1 mg/dL.⁶⁵ Nonetheless, studies have shown that diaphragmatic and skeletal muscle function may be adversely affected by more modest reductions in the phosphate concentration,^{66,67} and that hypophosphatemia may lead to impaired myocardial contractility.⁶⁸ The routine use of phosphate supplementation has not been demonstrated to alter morbidity or mortality and is not recommended.^{62–64}

Hyponatremia is seen in approximately two-thirds of patients with advanced DKA despite an osmotic diuresis and loss of water in excess of electrolyte. The presence of hyponatremia is due to the effect of hyperglycemia and hyperosmolality on the distribution of water in the intra- and extracellular compartments. Hypernatremia would be expected because of the osmotic diuresis and excretion of water in excess of solute, but the hyperglycemia holds a relative excess of water in the extracellular compartment and contributes to the persistence of hyponatremia until the water deficit is extreme. Thus a disproportionate amount of body water exists in the extracellular compartment in the face of volume contraction (hypovolemia). The shift of water from the intracellular to the extracellular compartment would be expected to produce a predictable lowering in the serum sodium concentration if the water remained exclusively within the extracellular compartment; however, because it is excreted in the urine, this relationship is less precise. As a rule, a 1.6–1.8-mEq/L reduction in the serum sodium concentration can be expected for every 100 mg/dL increase in the glucose concentration⁶⁹ (Table 34-2). Recently, it has been suggested that

the serum sodium decreases by ~ 2.4 mEq/L for hyperglycemia ≤ 400 mg/dL and by 4.0 mEq/L for glucose concentrations > 400 mg/dL.⁷⁰ These data suggest that the change in the serum sodium due to hyperglycemia is underestimated by using a factor of 1.6–1.8 mEq/L.⁷⁰ This approximation is valuable because it allows identification of those patients whose degree of hyponatremia is excessive for the prevailing hyperglycemia. Serum sodium concentrations that are less than 120 mEq/L are uncommon, and when present, suggest the presence of hypertriglyceridemia or other disorders that are associated with hyponatremia. In insulin-deficient states, lipoprotein lipase activity is decreased.⁷¹ This leads to a marked reduction in the clearance of triglyceride from the plasma. Serum sodium, potassium, and chloride levels are spuriously decreased in the presence of extremely elevated triglycerides.^{71–73} Similarly, “pseudonormoglycemia” has been reported.^{71–73} This occurs because electrolytes and glucose are present in the aqueous portion of plasma or serum, whereas concentrations are measured and reported per total volume of sample. In addition, some spectrophotometric methods and bedside blood glucose testing kits may underestimate the glucose value due to lipemic interference with assay methods.⁷² Ultracentrifugation of samples will allow the accurate measurement of electrolytes and glucose; however, this usually is not possible. It is essential that the laboratory report the presence of lipemia so that the spurious nature of unanticipated low concentrations of electrolytes and glucose can be appreciated.

Severe hyponatremia may be encountered in patients with end-stage renal disease in whom neither the glucose nor the water, which has shifted out of the cell, can be excreted. In such individuals, lowering the glucose concentration with insulin may be all that is necessary to correct the hyponatremia.⁷⁴ When the serum sodium concentration is normal or increased in a patient with DKA, lowering the serum glucose concentration may be associated with the development of hypernatremia, particularly in those patients who receive large volumes of isotonic saline. This is due to loss of water from the extracellular to the intracellular compartment as the glucose concentration falls and to the increased renal tubular reabsorption of sodium induced by volume contraction.

Although magnesium deficiency develops in patients with DKA,⁷⁵ the deficit is not usually significant. It is rarely associated with signs or symptoms, and generally corrects itself when a regular diet is resumed. Because magnesium deficiency impairs both the secretion and action of parathyroid hormone,^{76,77} patients may develop symptomatic hypocalcemia if they receive phosphate supplements.⁷⁸ The phosphate reduces the plasma ionized-calcium concentration, which cannot be restored to normal because of magnesium deficiency. Such patients require calcium supplementation to acutely correct symptomatic hypocalcemia and magnesium replacement to maintain a normal serum calcium.

Hyperamylasemia may occur in patients with DKA.^{79–81} Because DKA is often associated with abdominal pain, the presence of hyperamylasemia is of considerable clinical importance. Isoenzyme studies indicate that the amylase in DKA patients is frequently nonpancreatic in origin.⁸⁰ The presence of hyperamylasemia correlates poorly with abdominal complaints or physical findings in patients with DKA.^{79,80} In addition, hyperamylasemia may occur in 30% of patients with metabolic acidosis who do not have pancreatitis,⁸² indicating that it is specific neither for pancreatitis nor an intra-abdominal medical problem. Previously, if pancreatitis was suspected, a serum lipase measurement was obtained. However, the value of lipase measurements in DKA is uncertain. Marked hyperlipasemia, in the absence of clinical or radiographic

evidence of pancreatitis, has been demonstrated in patients with DKA.^{83,84} Total amylase levels are negatively correlated with bicarbonate levels and serum pH levels.⁸⁴ Pancreatic amylase and lipase correlate with glucose and BUN and are negatively correlated with serum bicarbonate levels.⁸⁴ The clinical evaluation of the patient is important with regard to the possibility of an intra-abdominal problem or pancreatitis. At the outset, signs and symptoms suggesting an intra-abdominal problem should be pursued aggressively. If there is hyperamylasemia, or hyperlipasemia, but there are no physical findings to suggest another intra-abdominal process, the patient should be followed carefully. The diagnosis of pancreatitis or an intra-abdominal process should be established based on appropriate clinical features. Abdominal pain commonly disappears in patients with DKA as the metabolic acidosis resolves.⁸⁵

BLOOD KETONES

In DKA, the plasma concentrations of β -hydroxybutyrate (B), acetoacetate (A), and acetone are increased. The ratio of B to A (B:A), representing the mitochondrial redox state, shows considerable interindividual variability; however, the mean value for the ratio is only mildly elevated when all patients with DKA are considered.⁸⁶ Infrequently, the B/A ratio may be very high and the acidosis due almost exclusively to β -hydroxybutyrate.⁸⁷ This is an important diagnostic problem because quantitative plasma ketone measurements are not routinely available, whereas qualitative tests, which detect acetoacetate, may be negative or weakly positive in this situation. The tendency toward a higher B:A ratio in DKA is attributed to the more reduced redox state of the cell that accompanies increased FFA metabolism. The increased B:A ratio may also reflect impairment of β -hydroxybutyrate conversion to acetoacetate and the reduced utilization of ketones that occurs with insulin deficiency. The B:A ratio is shifted toward β -hydroxybutyrate when a more reduced intracellular redox state exists, such as with lactic acidosis resulting from low flow and tissue hypoxia, or from the use of alcohol.⁸⁷ Patients with alcoholic ketosis may have significant ketosis, but a negative or weakly positive plasma ketone test.⁸⁸ The presence of a combined keto- and lactic acidosis could be overlooked under these circumstances.⁸⁷

Plasma acetone concentrations are markedly elevated in patients with DKA.^{89,90} Acetone, a water-soluble and freely diffusible compound, is distributed throughout total body water so that the acetone pool is markedly expanded. Acetone is of low toxicity, but in large concentrations may produce narcosis. It has been suggested that the drowsiness of some patients with DKA is due to high plasma acetone concentrations. The plasma acetone concentration may remain elevated for up to 48 hours, long after the glucose, β -hydroxybutyrate, and acetoacetate concentrations return to normal.⁸⁸ This likely explains the ketonuria that has been observed for several days following successful therapy of DKA.

Plasma and urinary ketones are detected and semiquantitated by the use of the nitroprusside reaction. The nitroprusside reagent does not react with β -hydroxybutyrate, and on a molar basis is only one-twentieth as reactive with acetone as with acetoacetate.⁹¹ Thus despite concentrations that are three- to fourfold greater than those of acetoacetate, acetone contributes only minimally to the color reaction. Acetoacetate, therefore, is the predominant determinant of the nitroprusside reaction. Thus, for a variety of reasons, this test correlates poorly with the degree of ketonemia. Additionally, sev-

eral drugs have been associated with false-positive tests using the nitroprusside reaction.⁹² Drugs that contain a sulfhydryl group such as captopril, dimercaprol, mesna, acetylcysteine, and penicillamine may give a false-positive result.⁹² Additionally, very high intake of ascorbic acid may cause urinary acidification and result in a false-negative nitroprusside reaction.⁹²

Recently, semiquantitative tests for β -hydroxybutyrate have become available. They are rapid and accurate and may be helpful in selected patient situations. To prevent the interference of acetoacetate with the measurement of β -hydroxybutyrate by the Keto-Site™ assay, the serum sample must be diluted.⁹³ Use of this test to define resolution of ketoacidosis (β -hydroxybutyrate ≤ 1.1 mmol/L) reveals that about one-half of patients still have positive serum Acetest™ results,⁹⁴ probably reflecting the slow elimination of acetone. Routine monitoring of ketones during treatment of DKA has not been shown to provide significant additional data to that provided by measuring the anion gap and glucose.

Following institution of therapy with insulin, the concentration of β -hydroxybutyrate decreases promptly while that of acetoacetate remains unchanged or increases slightly.⁸⁶ Later, the concentration of acetoacetate also decreases, reflecting the improved metabolic status. The preferential decrease in β -hydroxybutyrate reflects both decreased production and increased utilization. The shift in B:A ratio, however, particularly when the concentration of acetoacetate increases, accounts for the clinical observation that the plasma or urine Acetest reaction may become positive if initially negative, or more positive during the early phases of therapy.

TREATMENT OF DIABETIC KETOACIDOSIS

Successful treatment of DKA requires vigilant patient care as well as the use of effective doses of insulin, correction of volume deficits, and appropriate electrolyte supplementation. Adherence to these guidelines has resulted in a significant reduction in mortality from DKA (Table 34-7).

Until 1972, large doses of insulin were used in the treatment of DKA. The initial insulin dose and all subsequent doses were determined by the degree of hyperglycemia, the severity of the acidosis and ketonemia, or both. Complicated schemes were developed for the selection of insulin doses. Large doses of insulin were thought to be necessary because of the transient increased insulin resistance that resolved during therapy in most patients. In 1973, articles appeared in the literature demonstrating the effectiveness of small doses of insulin administered either by continuous intravenous infusion or intramuscularly. Most authorities recommend the use of low-dose insulin therapy for the treatment of DKA.

Although patients have been treated successfully with as little as 2 U of regular insulin per hour by continuous intravenous infusion, such doses provide an unacceptable rate of glucose reduction and are not recommended.⁹⁵ Despite variable rates of insulin administration, low doses (5–10 U/h, intramuscularly or intravenously) are effective in the treatment of most DKA patients. Although the rate at which the glucose concentration decreases varies considerably from patient to patient, it is fairly constant in any given patient. The average decline in the blood glucose concentration is 75–100 mg/dL/h and occurs at a predictable rate. Insulin can be administered either intramuscularly or intravenously, and at these doses produces plasma concentrations that are well within the maximum physiologic range (100–200 μ U/mL).^{96,97} Although most patients respond to these doses of insulin, there are some who

will not. Patients who are resistant to low doses of insulin can be identified prospectively by any clinical or laboratory parameter; consequently, low-dose insulin regimens require monitoring of patients at hourly intervals so that those who fail to respond can be detected at the earliest possible moment.

In the majority of DKA patients, large doses of insulin (5 U/h) administered intravenously do not reduce the blood glucose concentration more rapidly than doses of 5–10 U/h.⁹⁸ In the presence of infection, the rate of decrease in the blood glucose may be reduced by 50% to approximately 50 mg/dL/h. During the course of therapy, the plasma glucose concentration reaches a target of 250–300 mg/dL in approximately 4–6 hours, whereas correction of the acidosis (pH ≥ 7.30 or a bicarbonate concentration of $\geq$ mEq/L) requires approximately 8–12 hours. During therapy, plasma ketone and bicarbonate concentrations change in a reciprocal fashion. The rate of resolution of hyperglycemia and ketoacidosis is not appreciably faster when high-dose and low-dose intramuscular regimens are compared⁹⁸ and is comparable to low-dose intravenous administration. Intramuscular insulin is no more effective than intravenous insulin when correction of hyperglycemia and acidosis is considered, and large doses may put patients at risk for hypoglycemia and hypokalemia.

Hypoglycemia and hypokalemia occurred in 25% of a group of patients receiving high doses of insulin during treatment of DKA. If the glucose and potassium levels are monitored carefully, these problems usually can be avoided. The tendency of patients treated with large doses of insulin to develop hypokalemia may reflect their greater predisposition to hypoglycemia and excessive reentry of potassium into the intracellular compartment as it accompanies glucose, or may be a reflection of the direct effect of insulin on cellular potassium uptake. Since the rates at which the acidosis and hyperglycemia are corrected are similar, with 50 U/h and 5–10 U/h, it seems unlikely that the tendency toward hypokalemia reflects the effect of pH on the distribution of potassium between the intra- and extracellular compartments.

The low-dose intravenous and intramuscular insulin regimens appear to be equally effective for resolving hyperglycemia and acidosis. However, intramuscular low-dose insulin administration is not recommended in the severely hypovolemic patient owing to unpredictable absorption. Subcutaneous insulin administration should not be used.

The early decrease in plasma glucose concentrations will be largely a consequence of fluid administration, and therefore cannot be used as an indication of the adequacy of the insulin dose. The blood glucose concentration may decrease by as little as 9 mg/dL or as much as 90 mg/dL/h from rehydration.⁹⁹ Adequate rehydration contributes significantly to the decrease in the blood glucose concentration, not only as a consequence of dilution of glucose in a larger volume and improved GFR, but because it may also diminish the stimulus to release glucose counterregulatory hormones. During the initial phases of therapy, rehydration alone and dilution of glucose in the glucose space may account for 30–50%, and perhaps as much as 50–75%, of the reduction that occurs in the glucose concentration.^{100–102} Glucosuria accounts for approximately 15–20% of the decrease in the glucose concentration when insulin and rehydration are used together.¹⁰³ The actual effects of insulin on glucose metabolism during treatment of DKA are rather small and are due primarily to inhibition of hepatic glucose production (accounts for 75% of insulin's effect) and not to increased glucose utilization (accounts for 25% of insulin effect).¹⁰²

TABLE 34-7 Therapy of DKA**INSULIN**

- 0.1 U/kg body weight regular insulin as intravenous bolus followed by 0.1 U/kg/h (5–10 U/h) thereafter as a continuous infusion until glucose concentration is 250–300 mg/dL and the pH $\geq$ 7.3 or $\text{HCO}_3^- \geq$ 18 mEq/L.
OR
10 U of regular insulin intravenously as a loading dose followed by 5–10 U/h intramuscularly.
- Decrease administration to 2–3 U/h when the plasma glucose is 250–300 mg/dL and the $\text{HCO}_3^- \geq$ 18 mEq/L.

FLUIDS

0–1 hour

1000–2000 mL 0.9% saline for prompt correction of hypotension/hypoperfusion.

1–4 hours

750–1000 mL/h 0.9% saline or 0.45% saline based on intake, urinary output, clinical assessment of volume status, and laboratory measurements.

Glucose

When the plasma glucose reaches 250–300 mg/dL, administer glucose at a rate of 5–10 g/h, either as a separate infusion or combined with saline.

ELECTROLYTE REPLACEMENT*Potassium (replace as the chloride or phosphate)[†]

Assure urinary output prior to potassium supplementation

Maintain K^+ between 4 and 5 mEq/L $\text{K}^+ > 5.0$ mEq/L; no supplementation $\text{K}^+ = 4\text{--}5$ mEq/L; 20 mEq/L of replacement fluid $\text{K}^+ = 3\text{--}4$ mEq/L; 30–40 mEq/L of replacement fluid $\text{K}^+ \leq 3.0$ mEq/L; 40–60 mEq/L of replacement fluid

Phosphate

Not routinely recommended; if indicated, 30–60 mmol of phosphate as potassium phosphate (K_2PO_4) over 24 hours.

Magnesium

If $\text{Mg}^{++} < 1.8$ mEq/L or tetany present, give magnesium sulfate (MgSO_4), 5 g in 500 mL 0.45% saline over 5 hours.

Calcium

For symptomatic hypocalcemia, give 10–20 mL of 10% calcium gluconate (100–200 mg elemental calcium as indicated).

Bicarbonate

Not routinely recommended in the treatment of DKA. Consider if other indications present.

LABORATORY

Comprehensive admission profile

Arterial blood gases

Serum/urine ketone measurements

Check glucose every hour[‡]Check electrolytes every 4 hours[‡]Check Ca^{++} , Mg^{++} , phosphate every 4 hours

Cultures of blood, urine, sputum as indicated

GENERAL CARE

ECG prior to administration of supplemental potassium

Review urine output, vital signs, neurologic status, and laboratory data hourly

Frequent assessment of clinical status and repeat physical examination

Protection of the airway in the unconscious patient

Nasogastric suction as indicated for ileus, emesis, or obtundation with vulnerable airway

Chest radiograph and other imaging studies as needed

Consider CVP, Swan-Ganz catheterization in selected patients

* Drug doses should be modified in the patient with significant renal impairment.

[†] Dosage suggested using KCl.[‡] Modified as necessary depending on clinical assessment.Source: Modified with permission from Ennis *et al.*⁵

Changes in systemic pH usually do not occur for at least 1–2 hours after the onset of therapy.¹⁰³ Therefore, it is reasonable to continue the same dose of insulin for approximately 3–4 hours. If there has not been a substantial reduction in the glucose concentration and improvement in pH, larger doses of insulin should be used.

The success of low-dose insulin regimens is somewhat difficult to understand in light of previous claims that patients with DKA were severely insulin-resistant. The aggressive use of fluids in the therapy of patients may have contributed to the apparent sensitivity of patients to low doses of insulin. If fluid deficits are inadequately addressed, persistent hypovolemia continues to stimulate the re-

lease of counterregulatory hormones as well as impair glucose excretion in the urine. The sensitivity of patients with DKA to relatively low doses of insulin should not be interpreted to mean that these patients are insulin-sensitive and that no insulin resistance exists.¹⁰⁴ Patients with DKA who receive 5–10 U/h of insulin are obviously insulin-resistant. In a normal subject, the infusion of insulin at a rate of approximately 8 U/h requires the concomitant administration of 40 g of glucose per hour to maintain a constant blood glucose concentration.¹⁰⁴ When a normal subject is made hyperglycemic, but infused with somatostatin to prevent the release of endogenous insulin, the administration of exogenous insulin at a rate of 6 U/h is associated with a glucose disposal rate of about

60 g/h.¹⁰⁴ Thus 6–8 U/h can effectively metabolize 40–60 g of glucose per hour. In patients with DKA who are receiving insulin at 6–10 U/h, the glucose disposal rate is approximately 10 g/h, half of which is excreted in the urine.¹⁰⁴ Thus DKA patients are only one-tenth as insulin sensitive as nondiabetic patients.

The mechanisms of the insulin resistance in DKA patients are poorly understood. Glucose counterregulatory hormone levels are markedly increased in DKA. Hyperosmolality decreases insulin-mediated glucose utilization, but its effects are relatively modest.¹⁰⁵ Acidemia decreases receptor-mediated glucose metabolism, and phosphate deficiency produces a mild postbinding defect in glucose utilization.^{106,107} Ketoacids, independent of pH, may also induce a postbinding abnormality in insulin action.¹⁰⁶ Therefore, the resistance may be multifactorial.

A rare cause of extreme insulin resistance in patients with DKA is the presence of anti-insulin antibodies that bind insulin. Since the maximum biologic response to insulin is significantly reduced in the postbinding type of insulin resistance, and because resistance resolves slowly, it is not clear how or why large doses of insulin overcome unusual insulin resistance within the brief period of treatment of DKA. Changes occur slowly (over 96 hours) in insulin sensitivity and in glucose metabolism following the achievement of euglycemia.¹⁰⁸ This leads to the frequent clinical observation that it takes more insulin to get patients under control than to keep them in control.

The discrepancy between the rates of correction of hyperglycemia and acidemia has important clinical implications. Insulin administration must be continued despite relative euglycemia until the pH and bicarbonate targets have been achieved. Consequently, glucose must be administered to “buffer” a further decrease in the glucose concentration during the continued administration of insulin. Because glucose disposal is 5–10 g/h under these circumstances, glucose should be administered initially at these rates. If the glucose concentration increases, then the rate of glucose administration should be reduced; if the glucose concentration continues to decrease, additional glucose is needed. Occasionally, the plasma glucose concentration is less than 300 mg/dL at the initiation of therapy and glucose must be incorporated into the initial fluids used for correction of hypovolemia. Although there has been considerable discussion over whether hypotonic or isotonic fluid should be used in DKA, most would agree that hypovolemia should be corrected with isotonic saline, 2–4 L. Thereafter, the decision to use 0.45% or 0.9% saline solution should be guided by hemodynamic considerations, fluid balance, and the prevailing serum sodium and chloride concentrations. In adult patients without severe volume deficits, a lower rate of saline infusion is associated with more rapid recovery of the plasma bicarbonate.¹⁰⁹

Alternative intravenous solutions containing magnesium, potassium, and reduced chloride content (i.e., Plasmalyte™, Travenol/Baxter) have been advocated for use in the DKA patient, to provide a solution that closely resembles physiologic fluid replacement.^{110,111} Their use is not routinely recommended. Insulin should be administered at a rate that ensures optimum or slightly greater than optimum concentrations of plasma insulin (100–200 mU/mL). This can be attained by administration of intramuscular or intravenous insulin at a rate of 5–10 U/h, particularly if an intravenous loading dose is administered as part of the intramuscular regimen. Formerly, recommendations advised that insulin be diluted with protein-containing solutions (plasma or albumin) to minimize the loss of insulin by adsorption to glassware and plastic tubing. This is unnecessary because the insulin-adsorbing capacity

of plastic tubing can be saturated by discarding 50–100 mL of 5-U/dL insulin solution. If this technique is not used or protein not added to the solution, a lower rate of insulin administration is required and may contribute to apparent insulin resistance.

Adjuvant therapies for severe insulin resistance are being explored. Reports have described the use of octreotide to suppress α -glucagonogenesis in resistant T1DM patients.¹¹² Octreotide administration suppresses endogenous glucagon secretion, thereby ameliorates the permissive effects of glucagon on the development of DKA. Recently, octreotide (50 μ g every 6 hours subcutaneously) has been shown to improve resolution of ketonuria in DKA patients. Suppression of glucagon release is a principal mechanism by which this occurs.¹¹³ However, there was no improvement in time to resolution of the DKA-associated hyperglycemia and a dose.¹¹³ Therefore, the use of octreotide cannot be advocated as adjunct therapy for DKA. Treatment of severe insulin-resistant DKA with IGF-1 (insulin-like growth factor 1) has been found to reverse the hyperglycemia and ketoacidosis and to improve insulin sensitivity in a single patient.¹¹⁴

ACID-BASE CHANGES DURING THERAPY

Systemic pH is unchanged during the first hour after starting therapy with insulin and fluids.¹⁰³ Thereafter, the pH begins to increase, and by 6–12 hours it is usually between 7.25 and 7.35.⁴ After 24 hours, the systemic pH is normal or near-normal, but arterial PCO_2 and bicarbonate are still reduced, a pattern consistent with compensated mild metabolic acidosis. It is unusual for the respiratory rate and therefore the PCO_2 to normalize during the first 24 hours, because the respiratory center continues to drive ventilation.¹⁰³ Alkalosis should be avoided because it reduces cerebral blood flow and increases the affinity of hemoglobin for oxygen thereby reducing oxygen delivery to tissues. It also predisposes to hypokalemia and hypophosphatemia.⁶⁵

There is some controversy concerning the routine use of bicarbonate in the treatment of DKA. Under normal circumstances, the pH of the intracellular compartment is substantially lower than that of the extracellular space and is relatively well protected against the adverse effects of acidemia in acute metabolic acidosis. Whereas bicarbonate equilibrates slowly across the cell membrane, CO_2 equilibrates rapidly. Thus when extracellular pH falls, respiration is stimulated and the PCO_2 decreases, minimizing intracellular pH changes. In fact, intracellular pH may actually increase acutely. While hepatic intracellular pH is markedly reduced in DKA owing to the production of metabolic acid at that site, other cells within the body are initially protected against the adverse effects of acidemia.

Because hemodynamic abnormalities begin to appear when the pH falls below 7.1–7.2, bicarbonate use may be considered in patients with acidemia of this severity.^{115,116} On the other hand, some investigators do not recommend bicarbonate supplements unless the pH is less than 7.0.¹¹⁷ In retrospective studies, no significant differences could be demonstrated with regard to correction of hyperglycemia, acidosis, and level of consciousness among patients treated with bicarbonate and those not treated with bicarbonate.^{118–120} Interestingly, both ketone and lactate concentrations decreased more slowly in the patients who were treated with bicarbonate, but were of no apparent clinical consequence.¹¹⁹ In a more recent prospective randomized study of 21 patients with severe DKA, bicarbonate had no effect on recovery or other metabolic

parameters.¹²¹ In a recent retrospective study of patients with severe DKA (pH values between 6.83 and 7.08), bicarbonate therapy (120 mEq $\pm$ 40 mEq) did not improve the time to DKA resolution.¹²² However, the patients treated with bicarbonate required significantly greater potassium supplementation for hypokalemia during therapy.¹²² Thus the routine use of bicarbonate in DKA appears to offer no therapeutic advantage. It should be noted, however, that in those patients with a marked reduction of the bicarbonate concentration and maximal respiratory compensation, any further reduction in the bicarbonate concentration is associated with a drastic shift in pH. Consequently, the use of small quantities of bicarbonate in individuals whose plasma bicarbonate is of the order of 5–10 mEq/L might be prudent. In addition to exacerbating hypokalemia, it is reasonable to ask whether there is a theoretical disadvantage to the use of bicarbonate. Bicarbonate has been demonstrated to increase ketoacid production in the setting of starvation.^{123,124} Bicarbonate supplementation of subjects fasted for 5–7 days increased the plasma ketone concentrations as well as urinary ketoacid excretion, indicating that bicarbonate increased ketoacid production.¹²⁴ The exact mechanism for this effect is not clear, but is associated with a reduction in urinary nitrogen excretion and may be a mechanism by which protein breakdown is minimized in the fasting subject. The lack of effect of bicarbonate treatment on pH as well as the slower rate of decrease of the plasma ketone concentrations is consistent with these observations and suggests that bicarbonate may have increased ketoacid production. Although there may be a theoretical advantage to using bicarbonate in fasting subjects to minimize protein breakdown, there is no therapeutic advantage in the setting of DKA.

Patients recovering from DKA commonly demonstrate hyperchloremia and develop a non-anion-gap metabolic acidosis.^{54,125} During the treatment of DKA, the anion-gap metabolic acidosis resolves quickly and is replaced by a mixed metabolic acidosis in which features of both an anion-gap and a hyperchloremic metabolic acidosis are present. The hyperchloremic metabolic acidosis begins to develop with therapy, and evolves progressively until it becomes the dominant acid-base disturbance. During the course of recovery, patients with a hyperchloremic metabolic acidosis at presentation may have a lower final bicarbonate concentration than those who present with the typical anion-gap metabolic acidosis.⁵⁴ The development of the hyperchloremic metabolic acidosis during the recovery phase is attributed to several factors: (1) The bicarbonate and buffer deficit in such patients is greater than is apparent from the reduction in the plasma bicarbonate concentration because buffer in bone and other tissues has also been lost; (2) the availability of substrate (ketones) for regeneration of bicarbonate is less than that required to stoichiometrically replace the buffer that has been lost, because considerable quantities of ketones have already been lost in the urine; (3) rapid volume expansion further increases the excretion of ketones in the urine, accentuating the deficit in substrate availability required to regenerate bicarbonate; (4) increased proximal tubular chloride reabsorption occurs, owing to limited bicarbonate availability; and perhaps, (5) if volume replacement is excessive, there is also decreased proximal tubular reabsorption of bicarbonate. Though persistence of acidemia in the early phases of the treatment of DKA is an indication for the continued administration of insulin, it is important to recognize that this recommendation does not hold for the hyperchloremic metabolic acidosis that emerges toward the end of active therapy when the other metabolic abnormalities have been corrected. When the hyperglycemia has been controlled, the pH has reached

7.3, and the patient is feeling well without any signs or symptoms of DKA, the rate of insulin administration can be reduced. The acquired hyperchloremic metabolic acidosis will resolve over several days as the kidneys adjust acid secretion and bicarbonate is regenerated.

ALTERATIONS IN CENTRAL NERVOUS SYSTEM FUNCTION AND STRUCTURE

There has been great interest in the central nervous system of patients with DKA. This is a result of the infrequent but devastating development of cerebral edema in some patients recovering from DKA.¹²⁶ Though rare, the syndrome of cerebral edema usually occurs during treatment of the first episode of ketoacidosis, but its mechanisms are poorly understood. Neurologic collapse may occur as early as 3.5 hours after implementation of therapy or as late as 22 hours. Neither hyponatremia nor the rate of fluid administration appears to be a precipitating factor. Most patients have corrected sodium concentrations (130 mEq/L), and cerebral edema has developed in patients who were rehydrated with oral fluids. Excessive lowering of the glucose concentration during therapy is probably not important, since it is less than 200 mg/dL in only ~25% of patients who develop this complication.¹²⁶ An etiologic role for the rate at which the hyperglycemia is corrected cannot be demonstrated.

During the course of therapy of DKA, the cerebrospinal fluid pressure increases to high levels without any obvious adverse effect.¹²⁷ The increase in pressure occurs during the first 10 hours of therapy, and values as high as 600 mm H₂O may be reached without fatal outcome. Papilledema is not observed. The cerebrospinal fluid pressure returns to normal within 9–10 hours. The complication of cerebral edema, if it develops, will usually do so within 14–16 hours of the initiation of therapy.¹²⁶

In patients with coexistent hyponatremia, the plasma osmolality may be normal or just modestly elevated despite the presence of severe hyperglycemia. Correction of hyperglycemia during therapy without simultaneous elevation of the plasma sodium concentration permits adverse osmolar gradients to be created that favor the shift of fluid into the intracellular compartment of the brain and the development of cerebral edema. Careful intake and output measurements indicate that simple fluid overload is unlikely to be responsible for this problem. Large doses of glucocorticoids or mannitol or both¹²⁸ have been recommended as therapy, but there is little experience with the problem and it is difficult to know whether such an approach is beneficial.

Several theories have been proposed to explain this phenomenon. Paradoxical development of cerebrospinal fluid/central nervous system acidosis during treatment and altered central nervous system oxygenation resulting from increased hemoglobin affinity for oxygen and diminished cerebral blood flow during treatment of DKA seem unlikely causes of this complication. Development of an unfavorable osmotic gradient during therapy that favors excessive intracellular movement of water and overhydration of the central nervous system is the most plausible theory, but there are serious limitations with this theory as well.

The hypothesis has been postulated that the cerebral edema that occurs during the treatment of DKA is due to activation of the sodium-hydrogen exchanger in the cell membrane that regulates cytoplasmic pH.¹²⁹ Cytoplasmic acidification from high levels of organic acids activates sodium-hydrogen exchange, cellular

sodium entry, and the exit of hydrogen from the cell. Cell volume increases and swelling occurs as a consequence of acidification of the cytoplasmic compartment. The hypothesis suggests that the cell swelling is asymptomatic prior to the initiation of therapy. During therapy, extracellular proton concentrations fall, thus decreasing the competition between extracellular sodium and hydrogen for transport, sodium uptake increases, and osmotic swelling occurs. Correction of the hyperglycemia produces a decrease in the extracellular osmolality that further accentuates the osmolar gradient between the extracellular and intracellular compartment and favors the movement of water into the cell. Last, insulin may also directly activate the exchanger on the surface of cells, thereby aggravating central nervous system swelling. Other investigators have disputed this theory.¹³⁰ At present the hypothesis remains unproved and little additional information is available.

The theory that unfavorable osmotic gradients develop during DKA therapy is more strongly supported than any other at the present time. In dogs, sudden correction of sustained hyperglycemia leads to increased cerebrospinal fluid pressure and cerebral edema. The theory that sustained hyperglycemia produces increased quantities of central nervous system sorbitol via the polyol pathway, and that the accumulation of this slowly metabolizable sugar within the brain results in cerebral edema when the blood glucose concentration is abruptly reduced, is not entirely correct. Measurement of sorbitol and other osmotically active sugars in brain tissue reveals that there are insufficient quantities of these substances to account for the increased intracellular osmolality that develops in the face of sustained hyperglycemia. Several interesting observations relevant to this theory are derived from studies in rabbits.^{131,132} Acute hyperglycemia in rabbits will initially produce a loss of water from the brain and intracellular volume contraction. When the hyperglycemia is sustained, however, central nervous system volume and hydration are restored to normal. Thus mechanisms that protect the brain from water loss in the presence of sustained hyperosmolality appear to be operative.¹³³ The identity of these osmotically active particles, originally thought to be sorbitol but subsequently disproved, is still unknown, and they have been referred to as "idiogenic" osmoles.^{131,134} In a rat model of streptozocin-induced DKA, preservation of brain water content despite severe volume depletion is partly explained by an increase in brain taurine content.¹³⁵ Taurine has been previously shown to function as an osmoprotector in several mammalian brain models. Additionally, its role as an inhibitory neurotransmitter, increasing the seizure threshold, may be important in DKA.¹³⁵

When the blood glucose concentration is reduced by insulin from 55 mmol/L to less than 14 mmol/L (~300 mg/dL) over 4–6 hours, cerebral edema ensues. When the osmotic gradient between the brain and plasma is greater than 30 mOsm/kg, cerebral edema develops;¹³⁶ this gradient does not occur unless the blood glucose concentration is reduced to less than 14 mmol/L within 4 hours.¹³¹ It is particularly interesting that cerebral edema does not develop when dialysis is used to reduce the blood glucose concentration instead of insulin.¹³¹ With insulin, brain osmolality falls more slowly than plasma osmolality, favoring the formation of a significant gradient. In contrast, the decline in intra- and extracellular osmolality is parallel and proportional with dialysis. When insulin is used to correct the hyperglycemia, brain tissue analysis reveals that 50% of the osmotic gradient is due to electrolytes, including potassium, and 45% is due to unidentified particles. Brain water, sodium, and potassium are significantly increased by insulin. In view of its effects on electrolyte transport in other tissues, insulin may be im-

portant in the pathogenesis of this problem.¹³⁷ The recommendation that the glucose concentration not be acutely reduced to less than 250–300 mg/dL during the active phase of treatment of DKA is derived from these studies. Nonetheless, cerebral edema has developed in patients whose plasma glucose concentrations remained above 250–300 mg/dL.¹²⁶

Cerebral edema is often unpredictable; however, 50% of patients in one series had prodromal headache, confusion, incontinence, changes in arousal and behavior, pupillary changes, blood pressure changes, bradycardia, disturbed temperature regulation, or seizures.¹³⁰ Therapy was successful in 50% of patients who had premonitory symptoms.¹³⁰ The development of headache or confusion during the course of therapy, particularly in a young patient or one being treated for the first episode of DKA, suggests incipient cerebral edema and the need for aggressive intervention. These symptoms usually occur at a time when there has been considerable metabolic improvement. In a recent study of six children with DKA, treatment was associated with mild cerebral edema in all patients, but none developed neurologic signs or symptoms.¹³⁸ They received combinations of isotonic and hypotonic saline with glucose at rates of administration that varied from 3.1–7.95 L/m²/24 h. Computed tomography demonstrated narrowing of the third and lateral ventricles, with a reduction in the subarachnoid space. Sensory evoked potentials may be prolonged within 2 hours after starting therapy for DKA in patients without obvious clinical manifestations, suggesting transient dysfunction during treatment.¹³⁹ Thus cerebral edema may be a common subclinical occurrence during the course of treatment of DKA. If this supposition is true, then the difference between those who do and those who do not develop symptomatic cerebral edema is quantitative and not qualitative. All patients may develop cerebral edema, but only those with the greatest degree of cerebral edema are likely to have clinical complications. The issue of cerebral edema has been recently reviewed and its cause remains controversial and unresolved.^{140–142}

MISCELLANEOUS COMPLICATIONS

It is well known that the PO_2 of patients presenting with DKA is significantly elevated and may decrease dramatically during the course of therapy.¹⁴³ Hypoxemia has been noted in 53% of patients during the treatment of DKA. In association with the marked reduction that occurs in plasma colloid oncotic pressure during therapy, the arterial PO_2 may decrease by a mean of 33 mm Hg and the PAO_2 – PaO_2 gradient may indicate pulmonary dysfunction, of which pulmonary edema may be one of several causes. The development of noncardiac pulmonary edema as a complication of DKA treatment has been described.¹⁴⁴ A reduction in plasma oncotic pressure in combination with reduced pleural pressure may predispose the patient to the development of pulmonary edema. Pulmonary edema has also been described in patients with chronic renal failure during therapy of DKA.¹⁴⁵

Aspiration of gastric contents with subsequent respiratory problems or death is a rare complication of the treatment of DKA.¹⁴⁶ Gastric decompression may prevent this complication in selected patients.

The presence of hypothermia in patients with DKA is associated with a poor outcome. Despite hypothermia or absence of temperature elevation, a search for infection and consideration of concomitant endocrinopathy (i.e., myxedema) as a precipitating event for DKA is warranted. Mortality rates of 30–60% have been

encountered in hypothermic patients.^{147,148} Fulminant malignant hyperthermia has also been associated with DKA and coma.¹⁴⁹

MORBIDITY AND MORTALITY

There is a common misconception that the mortality rate in DKA is low. Because a substantial number of patients with DKA are elderly, some mortality is expected.^{6,150} Intercurrent illnesses are likely to be more serious in elderly patients with coexistent multi-system disease. In the elderly, the intercurrent illness is often the factor limiting survival, not the ketoacidosis.

Although the mortality rate of DKA has decreased, in 1994 DKA was the primary cause of 20 deaths per 100,000 diabetic patients.¹ There remains an excess DKA burden in the African-American population, which has a 2.3-fold increase in DKA.¹ Educational and economic resources must be allocated to this segment of the population to improve the mortality rate from DKA.^{151,1} Fortunately, children under age 15 years rarely have fatal DKA¹⁵¹ unless cerebral edema develops. Above the age of 15 years, DKA mortality increases progressively, reaching 15–28% in patients over the age of 65 years.¹⁵⁰

Although coma is now infrequently encountered in patients with DKA, its presence is a bad prognostic sign and high mortality should be expected.³ Mortality may approach 45% when coma is present.¹⁵⁰

Prevention of DKA through improved recognition of precipitating factors, early diagnosis and therapy, and education should decrease the incidence of DKA and further improve its associated morbidity and mortality.

Hyperglycemic Hyperosmolar Syndrome

Robert Matz

In 1886 Dreschfeld¹ described two clinical types of a usually fatal acute or subacute complication of uncontrolled diabetes. The most common syndrome is now recognized as diabetic ketoacidosis. The less frequent form of the disease was typically seen in “older diabetics who are still stout and well nourished at the time of the attack”¹ and was characterized by a more insidious onset of drowsiness, eventuating in frank coma. This entity was sporadically recognized by clinicians² under a variety of names, and is now best characterized as the *hyperglycemic hyperosmolar syndrome* (HHS).³

DEFINITION

The entity is characterized by severe hyperglycemia (plasma glucose ≥ 600 mg/dL or ≥ 34 mmol/L), hyperosmolarity (effective osmolarity ≥ 320 mOsm/L), and dehydration in the absence of significant ketoacidosis (the presence of some ketonuria or mild ketonemia and an arterial pH as low as 7.3 or a serum bicarbonate as low as 15 mEq/L do not preclude the diagnosis) (Table 35-1). It occurs more frequently in the elderly, often mild, type 2 diabetic; develops more insidiously than diabetic ketoacidosis (DKA); is frequently associated with central nervous system dysfunction; is typically associated with severe fluid depletion and renal functional impairment; and has been claimed to have an extraordinarily high mortality. It is part of a clinical spectrum of severe hyperglycemic disorders²⁻⁴ that ranges from hyperglycemic hyperosmolarity without ketosis to full-blown DKA, with a significant degree of overlap.

The term *diabetic coma* is a carryover from the preinsulin era, when coma was a frequent terminal event in the uncontrolled diabetic and over half of these patients on presentation were already comatose. Currently, only 10% of decompensated diabetics present in coma and more than 20% have no alteration of their state of consciousness. Any definition by laboratory values such as serum bicarbonate or serum ketone levels, plasma glucose, or serum osmolarity is arbitrary, and the term diabetic coma should be dropped.

HYPERGLYCEMIC HYPEROSMOLAR SYNDROME (HHS)

Early reports stressed the rarity and high mortality of HHS; however, pure hyperosmolar hyperglycemic diabetes is responsible for one-third to one-half of episodes of uncontrolled diabetes, and hy-

perosmolarity is present in an additional one-fifth to one-third of episodes, which we have termed *mixed HHS*.^{2,4} Therefore, 50–75% of uncontrolled diabetic patients present with significant hyperosmolarity.

Life-threatening hyperosmolarity is not restricted to patients with diabetes mellitus, and is seen, for example, in association with diabetes insipidus and in the elderly with a variety of illnesses, such as severe hyponatremia with a mortality exceeding 40%. Hyperglycemic hyperosmolarity may follow the administration of many medications or a variety of acute illnesses. The precipitants are similar to those responsible for DKA.³

While it has been called nonketotic and nonacidotic, this is incorrect since as many as half of the adults and most children with hyperglycemic hyperosmolarity exhibit some degree of metabolic acidosis, with an increased anion gap reflecting excess lactate, azotemia, or a mild degree of ketonemia.^{5,6}

The normal serum osmolarity is 290 ± 5 mOsm/L. A rough approximation of the actual value can be obtained as follows:

$$\begin{aligned} \text{Serum osmolarity (mOsm/L)} \\ = 2[\text{Na}^+ (\text{mEq/L}) + \text{K}^+ (\text{mEq/L})] \\ + \frac{\text{plasma glucose (mg/dL)}}{18} + \frac{\text{BUN (mg/dL)}}{2.8} \end{aligned}$$

In some calculations the serum K^+ is omitted.³ Because urea is freely diffusible across cell membranes, it contributes little to the effective serum osmolarity relative to the intracellular space, and is the effective osmolarity that is the critical determinant in hyperosmolar states. While HHS is referred to as “hyperosmolar” diabetes, the distinction should be made between osmolarity, which is the concentration of an osmolar solution, and tonicity, which is the osmotic pressure of a solution. Tonicity more appropriately reflects what we refer to as the *effective osmolarity* or Eosm.⁵

The effective serum osmolarity (Eosm) is calculated as follows:

$$\begin{aligned} \text{Eosm} = 2[\text{Na}^+ (\text{mEq/L}) + \text{K}^+ (\text{mEq/L})] \\ + \frac{\text{plasma glucose (mg/dL)}}{18} \end{aligned}$$

When Eosm exceeds 320 mOsm/L, significant hyperosmolarity exists; when Eosm exceeds 350 mOsm/L, severe hyperosmolarity is present.

TABLE 35-1. Hyperglycemic Hyperosmolar Syndrome

• Blood glucose ≥ 600 mg/dL or ≥ 34 mmol/L
• Eosm ≥ 320 mosm/L
• Arterial pH ≥ 7.30
• SERUM BICARBONATE > 15 mEq/L
Eosm = Effective osmolality
$= 2 [\text{Na}^+ + \text{K}^+ (\text{mEq/L})] + \frac{\text{Blood glucose (mg/dL)}}{18}$

Some authors omit the serum K^+ when calculating the Eosm.

PATHOGENESIS

Emphasis should be placed on the most common precipitants of uncontrolled diabetes. Infection,^{3,5} omission or withdrawal of insulin from known diabetics, lack of adequate free water intake (vomiting, restraints, side rails, extremes of age, excessive seda-

tion), a variety of physiologic stresses, and a growing number of medications must be considered, sought, and corrected (Fig. 35-1). Social isolation, especially in the elderly, is a major predisposing factor.⁶

The hyperglycemic hyperosmolar syndrome is restricted primarily to the infirm, neglected, very young, very old, institutionalized (in hospitals and nursing homes), mentally deficient, or impaired patients, and those who cannot recognize thirst or express their need for water. It is also seen in patients with major unreplaced fluid losses, usually secondary to a massive glucosuric osmotic diuresis, and following gastrointestinal fluid losses with a limited intake. These patients typically have type 2 diabetes mellitus (T2DM) or are not known to have diabetes prior to the hyperosmolar episode. Rarely, this syndrome may present in a type 1 diabetic at any age.

The critical initiating event is the development of a persistent glucosuric diuresis. Glucosuria develops when the amount of glucose presented to the proximal tubule is greater than 225 mg/min.

FIGURE 35-1. Pathogenesis of hyperglycemic hyperosmolar syndrome.

To achieve this tubular load, the plasma glucose must exceed 180 mg/dL at a normal glomerular filtration rate (GFR) of 125 mL/min. This level is the plasma renal threshold for glucose (the level beyond which, at normal GFR, glucose first appears in the urine). As the GFR decreases with renal insufficiency or intravascular volume depletion, greater levels of plasma glucose will be necessary to provide a tubular load of 225 mg/min. Thus, at a GFR of 62.5 mL/min, the plasma glucose would have to exceed 360 mg/dL to achieve this tubular load. When the tubular load of glucose exceeds 320 mg/min (the tubular maximum for glucose reabsorption or T_{mG}), almost all of the glucose reaching the tubules above this amount is lost in the urine. As long as fluid intake is adequate and intravascular volume and GFR are maintained, loss of glucose above the threshold and the T_{mG} functions as a renal safety valve, by preventing accumulation in the extracellular fluid (ECF) of non-diffusible glucose and associated life-threatening hyperosmolarity. If the GFR is normal (180 L/d), the filtered load of glucose is 1800 g/d at a plasma concentration of 1000 mg/dL. Since the normal kidney is capable of reabsorbing about 500 g of glucose per day, approximately 1300 g of glucose would be excreted per 24 hours. Thus a normally perfused kidney will not permit marked hyperglycemia to be present even for short periods of time. Since most patients with HHS do not have renal failure after treatment, their GFR must be reduced by a reversible mechanism, namely a marked contraction of the extracellular volume. It is failure to maintain adequate renal function due to primary kidney disease or secondary to intravascular volume depletion and the associated fall in GFR that results in remarkable elevations of the plasma glucose.

These patients may not respond to the stimulus of thirst because of incapacity, confusion, stroke, or age. Often they are unable to take or retain fluids due to restraints, sedation, coma, nausea and vomiting, or diarrhea. They may be receiving hyperosmotic nasogastric tube feedings or total parenteral nutrition with inadequate provision of free water, or have impaired renal function with inability to concentrate their urine or respond to antidiuretic hormone and conserve water. In any event, they do not ingest or retain sufficient quantities of free water to meet the demands of the glucosuric osmotic diuresis. These patients are losing electrolytes plus water, but the losses of water exceed those of electrolytes.⁸ If these losses are not replaced, hypovolemia, intra- and extracellular dehydration, and hyperosmolarity develop, setting the stage for the sequence already outlined.

Some of these patients on presentation have an adequate urine output that declines to oliguric levels after plasma glucose levels are lowered to the 250–350-mg/dL range. Patients may suffer from the “latent shock of dehydration”⁶ that can be made manifest by rapid correction of hyperglycemic hyperosmolarity without adequate volume replacement. If the plasma glucose concentration falls rapidly, the intracellular space, which is severely depleted of water and in osmotic equilibrium with the extracellular compartment, takes up water freed by the metabolism of glucose along an osmotic gradient favoring the movement of water from the extracellular to the intracellular space. This leaves behind a contracted intravascular space with concomitant hypotension and oliguria. Prevention is achieved by the infusion of larger volumes of crystalloid solutions early in therapy or at the first recognition of the complication. Controlled studies have not demonstrated the superiority of colloid over crystalloid solutions in this situation, and show no evidence that albumin administration reduces mortality in critically ill patients with hypovolemia, while suggesting that it may actually increase mortality.⁹

There is an age-related reduction in renal concentrating capacity associated with a low-grade arginine vasopressin (ADH) resistance in the aged kidney.¹⁰ Additional changes that occur with age include a 30–50% decrease in GFR, renal blood flow (RBF), and lean body mass by age 70. The elderly also have a reduced total body water content. A young individual is approximately 70% water, whereas the elderly are 60% water by weight. This means that a 70-kg (155-lb) 30-year-old has 7–8 L more total body water than a 70-year-old of the same weight. The elderly have less total body water with which to buffer losses in water and changes in osmolarity, a decreased sense of or response to thirst at serum osmolarities which younger individuals are driven to drink, so they may not voluntarily drink water to correct significant hyperosmolarity and dehydration. Thus the elderly, for multiple reasons, are more vulnerable to and have limited ability to deal with an osmotic diuresis and any major loss of free water.

CLINICAL MANIFESTATIONS

The liver's ability to produce sugar in the diabetic exceeds 1 kg/day.⁶ This gluconeogenic-induced hyperglycemia causes a massive solute diuresis, total body water depletion, and intracellular dehydration resulting in the classic features of uncontrolled diabetes mellitus: polyuria and polydipsia leading to hypovolemia, hypotension, organ hypoperfusion, and tachycardia. The osmotic diuresis results in loss of glucose, water, and multiple electrolytes. In the hyperosmolar nonacidotic patient, the entire syndrome evolves over a longer period of time (usually days to weeks) as compared to classical DKA, and ketosis either does not supervene or is a minor part of the picture.

The typical patient is over 60 years old,^{3,4} but HHS may be seen in infants, children, or young adults.² Often the patient is not previously known diabetic or the disease is mild and managed by diet, an oral hypoglycemic agent, or a small amount of insulin. Presentation may include a depressed mental status. In our series² 45% of the patients presenting with an Eosm >350 mOsm/L were comatose. The history is one of days to weeks of increasing thirst, polyuria, and frequently, in the background, a disease such as stroke or renal insufficiency. Patients present with heavy glucosuria and minimal or no ketonuria or ketonemia. A history of weight loss, weakness, visual disturbances, and leg cramps during the preceding days or weeks may be elicited. Patients usually, but not invariably, appear severely ill. Physical examination demonstrates profound dehydration, poor tissue turgor, soft sunken eyeballs, cool extremities, and at times, a rapid thready pulse. In contrast to DKA, respirations are not Kussmaul in nature, and the aroma of acetone cannot be appreciated on the breath.

Nausea, vomiting, and abdominal pain occur less frequently than in DKA, while constipation and anorexia are occasionally seen. Gastric stasis and ileus is less frequent than in classical DKA. Hyperglycemia (levels >250 mg/dL) slows gastric emptying and gastric motility,¹¹ but cannot alone explain the nausea and vomiting seen in the uncontrolled diabetic. Mild gastrointestinal bleeding from hemorrhagic gastritis occurs in as many as 25% of patients. These findings are typically reversed by hydration and insulin. The occurrence of abdominal pain, tenderness, nausea and vomiting, lack of bowel sounds, and ileus in uncontrolled diabetes must not obscure possible intra-abdominal processes requiring urgent attention (e.g., mesenteric ischemia or cholecystitis). The response to therapy and the history are of critical importance.

Findings secondary to uncontrolled diabetes usually improve dramatically following the rapid infusion of fluids and insulin, and their development follows the onset of the symptoms of uncontrolled diabetes rather than preceding them. Another cause of abdominal pain and tenderness in the uncontrolled diabetic is fatty infiltration of the liver resulting in distension of Glisson's capsule. Liver function tests are abnormal in up to one-third of patients, and both liver functional abnormalities and hepatic size return to normal following treatment.

Hypothermia (rectal temperature $\leq 96.8^{\circ}\text{F}$ or 36°C , or an oral temperature below 95°F or 35°C) or normothermia is the rule in DKA,¹² and deep hypothermia is a poor prognostic sign in the presence of ketoacidosis.¹³ In HHS the average rectal temperature on admission in our series of 130 patients was 99.8°F (37.7°C) and in the fatal episodes 100.7°F (38.2°C).³

The dehydration encountered in the hyperosmolar patient has been thought responsible for the absence of physical (rales) or x-ray (infiltrates) evidence of pneumonia until rehydration is achieved, but this is a rarity and more often than not unauthenticated. However, evidence of congestive heart failure may be absent until the patient has been volume repleted. Therefore, patients with HHS should have a periodic repeat physical examination and, when indicated, x-ray examination, during the course of treatment.

The development of acute respiratory distress syndrome (ARDS) in uncontrolled diabetes has been fully described by Carroll and Matz,^{13,14} but has been seen in only one patient with pure HHS. Nevertheless, 75% of the patients with this complication have had an Eosm exceeding 320 mOsm/L.

Few patients with HHS or DKA now present in true coma, and many have no clouding of consciousness. Investigators¹⁵ have concluded that the depth of stupor in uncontrolled diabetes does not correlate with acidemia, but rather parallels the hyperglycemia and best correlates with the degree of hyperosmolarity. Acidosis has been claimed to correlate with the level of consciousness, but this relationship has not been confirmed.¹⁶ Hyperosmolarity is not sufficient for the development of stupor in these patients.¹⁵ The additional factor is the rapidity with which hyperosmolarity develops. Others¹⁷ have proposed that the serum sodium concentration corrected for the concomitant serum glucose concentration provides a better index of cerebral hydration and identifies patients at risk for neurological impairment.¹⁸ If the effect of urea is removed and the "effective osmolality" or "tonicity" is calculated, patients with Eosm levels of ≥ 320 mOsm/L may be comatose, whereas those with lower levels are typically not.

In summary, coma in the uncontrolled diabetic is primarily the result of hyperglycemia and hyperosmolarity and not acidosis. Coma rarely occurs unless the measured osmolality exceeds 340 mOsm/L⁵ or the Eosm is >320 mOsm/L,^{2,17} and most comatose or stuporous patients have an Eosm >350 mOsm/L. The absence of hyperosmolarity (in the absence of hypoglycemia) in an obtunded diabetic suggests that the alteration in consciousness is not due to metabolic decompensation, and another cause must be sought.

Patients with HHS present with neurologic abnormalities that are rarely observed in DKA not accompanied by hyperosmolarity.¹⁹ Up to 19% manifest grand mal or focal seizures and/or transient hemiparesis, and may have an extensor plantar reflex (Babinski) leading to the erroneous diagnosis of stroke. Additional findings may include aphasia, homonymous hemianopsia, hemisensory deficits, visual hallucinations, muscle fasciculations, opsoclonus-myoclonus, central hyperthermia, nystagmus, delirium, acute quadriplegia, and the exacerbation of a previous organic

mental syndrome.⁶ The neurologic signs may be focal, often reflecting sites of prior central nervous system damage. Most of these neurologic abnormalities resolve with correction of the hyperosmolarity. Seizures, when present, should not be treated with anti-convulsants, especially diphenylhydantoin, because anticonvulsants are relatively ineffective in metabolic seizures and diphenylhydantoin has been responsible for precipitating HHS.²⁰ Seizures usually respond quickly to correction of hyperosmolarity.

Hypotension may be present on admission or develop subsequently if body water and intravascular volume are not adequately repleted.⁶ This should be rare with early recognition of the syndrome and the more aggressive use of large volume infusions.

Vascular occlusions have been reported as the most important complication of HHS. These include mesenteric artery occlusion, low-flow syndrome, and disseminated intravascular coagulation. Arterial thromboses are claimed to be responsible for 33% of the deaths in comatose diabetics,²¹ and there is speculation about the potential benefits of using anticoagulants and inhibitors of platelet function in these patients.^{21,22} Recommendations for low-dose heparin in elderly comatose patients or those with severe hyperosmolarity have been made.⁶ We² have found the incidence of vascular occlusions to be low (2%), and these events occurred in the presence of severe hypotension, dehydration with associated hemoconcentration, and hyperviscosity associated with low flow in an already compromised circulation. Since platelet aggregation is increased in diabetic subjects,²³ insulin-mediated vasodilation via endothelial release of nitric oxide is impaired in insulin-resistant states, and both type 2 diabetes and insulin resistance are associated with impaired fibrinolysis²³⁻²⁵ and elevated plasminogen activator inhibitor-1 (PAI-1) levels, the invocation of an additional coagulopathy in HHS is questioned. Heme-positive gastric contents are seen in up to 25% of uncontrolled diabetes.⁶ If full anticoagulation becomes routine, an increase in the incidence and severity of gastrointestinal hemorrhage might ensue. Aggressive volume repletion and Mg^{++} replacement^{2,26} (which has a platelet antiaggregant effect) may account for the infrequency of thromboembolic complications in our series.² No prospective studies have demonstrated the safety or benefit of prophylactic full anticoagulation or of low-dose heparin. As in any acutely ill, bedridden, elderly patient with compromised circulatory status, underlying vascular disease, and a hypercoagulable state, low-dose heparin or low-molecular-weight heparin may be beneficial if there are no contraindications and the peripheral circulation is adequate to permit absorption. If there are specific indications for full anticoagulation, its use should be based on weighing the benefits versus the risks.

Rarely, pleural, pleuropericardial, and pericardial friction rubs and pain may occur in severely dehydrated patients with ketoacidosis, as well as in hyperglycemic hyperosmolar patients. Transient ST and T wave changes compatible with pericarditis may be seen in patients with HHS with DKA. These evanescent findings are typically seen on presentation and rapidly resolve with hydration.^{27,28}

LABORATORY FINDINGS

The laboratory characteristics of HHS are influenced by the criteria chosen for the definition. In two large series, the average plasma glucose was 998 mg/dL, HCO_3^- was 21.6 mEq/L, Na^+ was 143 mEq/L, K^+ was 5.0 mEq/L, and the anion gap was 23.4 mEq/L.

A polymorphonuclear leukocytosis with a count in the 12,000–15,000/ mm^3 range is the rule, and it may exceed 50,000/ mm^3 . In

most patients the hematocrit will be increased secondary to intravascular volume contraction, with values over 55% commonly seen. A normal hematocrit on presentation should lead the clinician to anticipate anemia when volume has been restored. When the mean corpuscular hemoglobin concentration (MCHC) and hematocrit are determined by the Coulter technique, results may be artificially elevated in patients with hyperosmolarity, since the diluting fluid used during the analysis is isosmotic with normal serum and will cause swelling of hyperosmolar red cells. Abnormal liver function tests and multiple abnormalities of a variety of serum enzymes have been seen in 20–65% of patients with either DKA or HHS. Patients with uncontrolled diabetes develop the “euthyroid sick syndrome,” with low levels of T_3 , T_4 , and TSH, plus elevated levels of reverse T_3 .²⁹ Triglyceride and cholesterol levels are elevated in uncontrolled diabetes. The serum may appear lactescent and lipemia retinalis on funduscopy may be present.

Lipemia may cause methodologic interference with a number of laboratory tests. The problem previously referred to as “pseudohyponatremia,” or a falsely low serum sodium seen in the presence of severely elevated triglycerides and chylomicrons when serum electrolytes were determined volumetrically, should no longer be an issue in laboratories where ion-specific electrodes are in use. Where older volumetric methods are utilized, pseudohyponatremia may still be seen.

The serum amylase may be elevated in DKA in the absence of acute pancreatitis, but this is uncommon in HHS, and in fact the amylase determination may be falsely low due to interference from serum triglycerides.

TREATMENT

Generally accepted aspects of therapy include searching for correctable precipitants, such as infection, and treating them promptly. In older patients and those with cardiovascular disease, a central venous line capable of monitoring the central venous pressure or a Swan-Ganz catheter is often warranted. If the patient is alert and capable of voiding, an indwelling urinary catheter should be avoided; however, in obtunded patients an indwelling catheter is necessary until they can void on demand, and urine output should be continuously monitored (Table 35-2).

Nasogastric intubation may be required since ileus, gastric distension, and mild gastrointestinal bleeding occur in a number of patients, and the obtunded patient is liable to vomit and aspirate gastric contents, further complicating therapy.

Neither body temperature nor white blood counts are reliable indicators of infection in these patients. Once appropriate cultures are obtained, if an infection is strongly suspected, conventional wisdom dictates antibiotic therapy.

If hypotension is present, large volumes of a crystalloid solution or a volume expander should be administered, and correction of hypoperfusion takes precedence over all other considerations. If necessary, pressors should be added to the regimen when the hypotension is refractory to volume replacement. When the hyperosmolar patient becomes hypotensive, there is no volume reserve to call upon since the hyperosmolar state has already effected maximum removal of water from the intracellular space to maintain the integrity of the intravascular compartment. This “autotransfusion” serves to preserve vascular volume and organ perfusion at the expense of intracellular volume.⁵ Therefore, when shock supervenes, water must be rapidly replaced to restore the integrity of the circula-

tion. If hypotension persists after large volume infusions and pressors, other causes must be considered (e.g., myocardial infarction, sepsis, pancreatitis, or gastrointestinal hemorrhage).

While insulin resistance is present in virtually every diabetic and although hyperosmolarity results in impairment of insulin-mediated glucose metabolism and reduced pancreatic insulin secretion,⁶ the large doses of insulin previously used to treat uncontrolled diabetes are unnecessary. If there is any question about adequacy of peripheral perfusion, the intravenous route of insulin administration is most reliable. The use of intramuscular or subcutaneous insulin is acceptable as long as perfusion of the injection site is adequate and the clinician remembers that both the onset as well as cessation of action of insulin given in this manner is delayed. Repetitive intravenous insulin bolus treatment of the uncontrolled diabetic is inefficient and unreliable. We recommend an intravenous bolus of approximately 10–15 U of regular insulin to provide a rapid blood level, followed by a continuous infusion of 0.1 U/kg/h (in the average adult, 5–10 U/h). With all reported regimens, the rate of plasma glucose decline is linear and predictable between 75 and 150 mg/dL/h, provided no other complicating features are present. The amount of insulin required to treat HHS is comparable to that required in DKA.

Once intravenous insulin is discontinued and intermittent subcutaneous insulin begun, management typically defaults to “sliding-scale” insulin coverage. This method of treatment has never undergone objective scrutiny and violates what is known about the physiology of insulin action, which indicates preemptive administration is needed to control hyperglycemia and repair metabolic chaos of the uncontrolled diabetic state. It is intellectually, intuitively, and practically impossible to regulate blood glucose retroactively, and sliding-scale coverage, while it relieves a tired physician of the necessity to contemporaneously evaluate each glucose level, delays the establishment of a suitable prospective treatment regimen and prolongs hospitalization.

Because of the “safety-valve” function of the normal kidney in the presence of plasma glucose concentrations exceeding the T_mG , significant hyperglycemia can occur only if RBF and GFR are reduced (in the absence of an obstructive uropathy). When uncontrolled diabetics are rehydrated and renal blood flow is reestablished, the loss of glucose in the urine should rapidly lower the serum glucose to a level somewhere between the renal threshold and the T_mG (i.e., between 180 and 350 mg/dL). Early in treatment the primary mechanism for glucose disposal is urinary excretion rather than insulin-mediated enhancement of glucose utilization. Three mechanisms account for the early fall in plasma glucose in HHS. Dilution by infused fluids accounts for 24–34% of the total reduction, while glucosuria in those with a preserved GFR and at least reduced ECF accounts for most of the reduction (a 29–76% fall in the glucose pool⁶). Raising the GFR in the presence of a high plasma glucose results in excretion of larger amounts of glucose. The remaining early fall in blood glucose concentration is due to non-insulin-dependent glucose metabolism in organs such as the brain and kidney.

The fall in plasma glucose concentration during the early hours of treatment serves as an index of the adequacy of rehydration and the restoration of renal blood flow. Failure of the plasma glucose to fall implies either inadequate volume expansion or renal functional impairment. Therefore, the clinician must be wary of patients with uncontrolled diabetes and renal failure. Patients with either HHS or hyperglycemia in the presence of renal failure may present with high plasma glucose, BUN, and

TABLE 35-2. Treatment of Hyperglycemic Hyperosmolar Syndrome**General**

- Perform directed history and physical examination.
- Obtain plasma glucose, P, K^+ , Ca^{++} , Mg^{++} , BUN, creatinine, electrolytes, CBC, urinalysis, chest x-ray, electrocardiogram, appropriate cultures, and ABGs.
- Aspirate stomach if patient is nauseated or vomiting, or if distention or bowel sounds are absent. Leave nasogastric tube in place on suction if large volume of gastric contents is obtained or if contents are guaiac-positive.
- Insert urinary catheter if unable to void or obtunded. Monitor urine output hourly.
- Administer thiamine and vitamin B complex IV.
- Administer antibiotics as appropriate for infection or suspected infection.
- Check for hypotension, state of consciousness (coma, stupor, or obtundation), hypothermia, or hyperthermia.
- Other directed studies as indicated (e.g., lumbar puncture if meningitis is suspected).
- Consider airway protection in obtunded or unconscious patients.

Fluids

- Administer 0.5 N electrolyte solution if Eosm >320 mOsm/L, at a rate of 1500 mL/h (15–30 mL/kg/h) for first hour, 1000 mL/h for second and third hours, and 500–750 mL/h for fourth hour.
- When Eosm <320 mOsm/L, crystalloid fluid prescription should be changed to 1 N concentration (isotonic).
- If hypotensive, give 2000 mL/h of electrolyte solution (osmolarity dependent on Eosm as above).
- If hypotension is unresponsive to crystalloids, consider use of colloid and pressors.
- May require central venous pressure and/or pulmonary capillary wedge pressure monitoring to guide treatment. (In complicated cases, monitoring of cardiac output, peripheral resistance, and other parameters may be essential.)
- Add 5% D5W when plasma glucose is 250–300 mg/dL.
- Caution! Reduce fluid administration in presence of renal failure.

Insulin

- Give 15-U regular insulin bolus intravenously followed by intravenous (or intramuscular or subcutaneous) infusion of regular insulin at a rate of 0.1 U/kg/h (5–10 U/h).
- Decrease dose to 2–3 U/h when plasma glucose is 250–300 mg/dL.
- If plasma glucose fails to decrease over 2–4 hours and urine output, fluid administration, and blood pressure are adequate, double insulin dose hourly.

Potassium

- Administer no K^+ if plasma $K^+ >5.0$ mEq/L.
- Administer 20 mEq/h of K^+ as one-half potassium acetate and one-half potassium phosphate if plasma K^+ is 4–5 mEq/L.
- Administer 40 mEq K^+ /h two times if plasma K^+ is 3–4 mEq/L, then administer 20 mEq/h while rechecking K^+ .
- Administer 60 mEq/h one time if plasma $K^+ <3.0$ mEq/L, and then 40 mEq/h one time while plasma K^+ is rechecked.
- Monitor ECG hourly (leads V_4 and V_5) for T waves to assist in guiding therapy between K^+ determinations.

Phosphate

- Administer 0.1 mmol/kg/h (5–10 mmol/h) to maximum of 80–120 mmol/24 h.
- If serum P falls below 1.0 mg/dL, increase infusion to 0.15 mmol/kg/h (10–15 mmol/h).
- If tetany develops, stop phosphate infusion, administer Ca^{++} /Mg $^{++}$, and check Ca^{++} and Mg $^{++}$ levels.
- Do not use in presence of renal failure.

Magnesium

- Utilize physiologic multielectrolyte solutions containing Mg $^{++}$ (3–5 mEq/L) as standard intravenous fluid vehicle.
- Administer 0.05–0.1 mL/kg of 20% $MgSO_4$ intramuscularly (or IV) (i.e., 4–8 mL of 20% $MgSO_4$ [0.08–0.16 mEq/kg]).
- If Mg $^{++}$ is low or tetany develops, administer 500 mL of 2% $MgSO_4$ solution intravenously over 4 hours plus additional IM doses of 6–12 mEq every 6–8 hours.
- Do not use in presence of renal failure.

Calcium

- If Ca^{++} is low or tetany develops, administer 10 mEq as an intravenous bolus and repeat as indicated.

Comments

- Repeat K^+ hourly or as indicated.
- Repeat Na^+ , venous bicarbonate, BUN every 2–4 hours.
- Once plasma glucose is <600 mg/dL, utilize bedside fingerstick blood glucose testing hourly to monitor. Confirm with chemistry lab values every 2–4 hours.
- Monitor blood pressure, pulse rate, temperature, and respiratory rate hourly until stable for 2–4 hours.
- Repeat pertinent physical exam as necessary, with special concentration on neurologic (mental) status; repeat exam of lungs for evidence of pneumonia, CHF, or ARDS; perform abdominal exam if NG tube has been inserted.
- Monitor intake and output hourly for at least 8 hours or until stable.
- Repeat pertinent tests as clinically indicated: ABGs, Hb/Hct, Mg, Ca^{++} chest x-ray.
- In the absence of contraindications, consider prophylactic low-dose heparin or low-molecular-weight heparin.

creatinine. If renal failure is unrecognized and rapid fluid replacement is begun, pulmonary edema and/or congestive heart failure is inevitable. For hyperglycemia accompanying renal failure, therapy with insulin alone, often in high doses, is appropriate. Insulin will reduce elevated potassium levels and as plasma glucose falls, the water freed will move out of the ECF into the intracellular space, thus decreasing the manifestations of circulatory congestion. Sudden loss of control of diabetes in the presence of advanced renal failure may cause pulmonary edema and life-threatening hyperkalemia, both reversible by the use of insulin alone.

The fluid losses in HHS range from 4.8 to 12.6 L with a mean of 9.1 L.⁶ The fluid lost is hypotonic with respect to electrolytes. Therefore, the losses should be replaced with a hypotonic electrolyte solution (0.45% NaCl or a 0.5 N balanced electrolyte solution). Half-normal balanced electrolyte solutions (e.g., Plasma-lyte™, Isolyte S™, Normosol™ or lactated Ringer's) avoid the administration of excess chloride that occurs when saline is used to replace the lost free water. Isotonic solutions, while initially hypotonic to the patient's serum, provide excessive amounts of sodium, and in the case of saline, excess chloride, resulting in hyponatremia or hyperchloremia while aggravating the tendency toward insulin-induced edema. The time has come to replace normal saline and 0.5 N saline with these physiological solutions in the therapy of the uncontrolled diabetic. Until the initial tonicity of the serum (Eosm) can be calculated, especially if the patient is hypotensive, isotonic fluid resuscitation with 1 or 2 L of crystalloid may be used. However, once evidence of significant hyperosmolality is obtained, hypotonic replacement is safe, effective, and sensible.^{3,30}

The arguments against the use of hypotonic solutions in HHS include the concerns that there will be too rapid a fall in ECF osmolality,²² that isotonic solutions are already hypotonic with respect to the hyperosmolar fluid compartment of the patient, and that isotonic saline provides a better means of maintaining adequate ECF volume. While isotonic saline initially lowers the osmolality, it provides more sodium and chloride relative to water than the hypertonic patient needs. As the water freed from the osmotic hold of glucose pours into the hyperosmolar intracellular space, the osmotically active particles of glucose are replaced by equally osmotically active sodium, with resultant prolongation of the hyperosmolar state and development of hyponatremia, which carries a 42% mortality rate,⁶ considerably greater than the mortality associated with hyperglycemic hyperosmolality of comparable severity. While early efforts at treatment and fluid replacement continue, the hyperglycemic hyperosmolar diabetic is still undergoing a massive osmotic diuresis that continually removes water in excess of electrolytes until the glucosuria is curbed. This adds to the body's need for free water without electrolytes or osmoles.³¹

Genuth³⁰ suggests that the increase in serum Na⁺ levels, sometimes to 160–170 mEq/L, during therapy of HHS and the occasional persistence of hyponatremia in the 150–155-mEq/L range for days after correction of hyperglycemia in some patients is associated with an elevated serum creatinine, high ADH levels, and unresponsiveness to exogenous AVP, all of which suggest temporary nephrogenic diabetes insipidus. In these patients provision of additional free water in the form of hypotonic solutions may be essential to correct the elevated Na⁺. Of course, D5W with sufficient insulin to maintain glucose metabolism will provide the necessary free water.

If isotonic replacement solutions are used initially, frequent monitoring of serum concentrations of sodium and chloride are essential to avoid replacing hyperglycemia with hyponatremia and

iatrogenic hyperchloremia. If hypotonic solutions are delayed later in treatment, by the time they are administered the intracellular space may no longer be as hyperosmolar as it was initially; it will no longer provide a sink for any excess infused fluid, paving the way for circulatory overload. Early in the therapy of a hyperosmolar dehydrated patient, the hypertonic intracellular space, which is huge in comparison to the ECF and intravascular space, acts like a sponge soaking up the fluid administered, preventing volume overload. This capacity progressively diminishes with fluid repletion, so that attempts to "catch up" and replace persistently elevated serum osmolarities late in the course of treatment are hazardous. The first few hours of fluid replacement are key to rapidly replacing water and electrolyte losses in their proper proportion.

The estimated total body water losses in HHS range between 100 and 200 mL/kg with an average of 150 mL/kg (Table 35-1). It must be emphasized that an aggressive volume replacement regimen must not be applied to the oliguric patient with renal failure and hyperglycemia. Several patients who developed pulmonary edema during the treatment of HHS have been successfully managed by infusion of distilled water into their central venous systems.³²

Electrolyte losses are a major component of the uncontrolled diabetic state.⁶ Sodium losses are 5–13 mEq/kg (average, 10 mEq/kg); chloride losses are 3–7 mEq/kg (average, 5.0 mEq/kg) and potassium losses are 5–15 mEq/kg, with the average requirement to fully replete potassium stores around 10 mEq/kg. The loss of phosphorus is about 70–140 mg, Ca⁺⁺ 50–100 mEq, and Mg 50–100 mEq.

Phosphate is lost as a result of vomiting, anorexia, and the glucosuric osmotic diuresis which precedes HHS, while concurrent hypokalemia and hypomagnesemia impair renal phosphate retention. Initial serum phosphate levels may be elevated, but with fluid and insulin therapy the serum levels fall even if phosphate deficiency is not present. Findings associated with hypophosphatemia include weakness, rhabdomyolysis, coma, convulsions, hyporeflexia, and hemolytic anemia. Symptoms of hypophosphatemia are never seen at serum levels above 2 mg/dL, and significant morbidity is rare unless the level is persistently below 0.5 mg/dL. We routinely administer monobasic potassium phosphate unless a specific contraindication exists. While a beneficial effect from the routine use of phosphate in the uncontrolled diabetic has not been demonstrated, this was studied in acute DKA, where the mean nadir of phosphate levels in those patients not given supplemental phosphate was only moderately hypophosphatemic.⁶ In HHS, where the development of the full-blown syndrome occurs over a longer period and is associated with a prolonged osmotic diuresis, phosphate stores may be more extensively depleted and warrant routine supplementation.³³ The most frequent cause of hypophosphatemia is internal redistribution commonly seen during glucose administration to nondiabetic hospitalized patients³³ resulting in increased insulin secretion, during recovery from uncontrolled diabetes, and during refeeding of malnourished patients. Intracellular redistribution occurs due to the formation of phosphorylated glycolytic intermediates, and when superimposed on the losses already incurred in chronically poorly controlled diabetics or malnourished patients, significant falls in the serum phosphate routinely occur. Repletion may be important to restore normal metabolic pathways and to prevent the occasional case of symptomatic severe hypophosphatemia. Since potassium and magnesium, the intracellular cations, do not readily enter the cell accompanied by chloride, an

alternative anion, phosphate, must be present to allow the timely restoration of the intracellular milieu.³⁴ Hypocalcemia, clinically manifested as tetany, may complicate the use of phosphate in DKA.⁶ We have never seen symptomatic tetany associated with phosphate administration and attribute this to routine use of magnesium replacement.²

Calcium losses in the 50–100-mmol range are common, and after 12 hours of treatment serum calcium levels tend to be at the lower end of normal. If phosphate replacement is given without magnesium, one may expect more frequent symptomatic hypocalcemia and the clinician must be alert to this possibility. Magnesium losses are common and tend to parallel those of potassium,²² but with the exception of an occasional episode of tetany associated with phosphate infusion, no clinical reports of symptomatic magnesium deficiency in diabetic coma are available. Glycosuria is associated with increased urinary losses of magnesium and low serum levels are found in decompensated diabetes after 12 hours of therapy. Symptoms ascribable to magnesium deficiency are primarily neurologic and include lethargy, weakness, mental changes, convulsions, stupor, and coma. Nausea, vomiting, and refractory cardiac arrhythmias may occur.⁶ The effects of magnesium and potassium deficiency are similar and may be impossible to differentiate. Indeed, potassium deficiency refractory to replacement therapy may be a result of a hypomagnesemic effect on the renal tubules, and hypocalcemia may also result from magnesium deficiency. We have noted the potential beneficial effects of Mg^{++} in prevention of thromboembolic events in the uncontrolled diabetic state. With recognition that the administration of Mg^{++} is safe, the evidence of its preventive effect on arrhythmias, possible platelet antiaggregation, and enhancement of K^+ retention, we currently routinely administer Mg^{++} to all uncontrolled diabetics unless renal failure or hypermagnesemia is present (Table 35-2).

Potassium losses in HHS occur due to the severe catabolic state and loss of intracellular water rich in potassium as part of the osmotic diuresis. Hypomagnesemia may worsen the potassium losses. The losses in HHS exceed those in DKA and, without replacement therapy, hypokalemia will be seen in most patients after 4–12 hours of treatment. The symptoms of hypokalemia are well known and include neuromuscular weakness, ileus, ECG abnormalities, cardiac conduction system defects, and rhabdomyolysis. Fatal hypokalemia is associated with cardiac arrest and respiratory paralysis. As treatment of uncontrolled diabetes continues, urinary potassium losses and those from nasogastric suction, especially if magnesium deficiency is present, may approach 50% of the amount being administered.

The objective of potassium replacement is to maintain normokalemia. The huge body deficits cannot and should not be replaced acutely. Total body deficits require days to weeks to completely correct. Even in the presence of renal insufficiency, early potassium replacement may be indicated, because with the exception of the urinary losses, all of the other factors that drive the serum potassium down in the treated diabetic are present. Caution must be exercised in patients with diabetic nephropathy, who may have renal tubular acidosis associated with hypoaldosteronism and hyporeninemia. Here serum potassium concentrations may be elevated and rise further when potassium is administered.

Potassium replacement begins in the first hour if urinary output is adequate, the ECG shows no evidence of hyperkalemic changes, and the serum K^+ is less than 5.0 mEq/L (Table 35-2). Potassium is given as the acetate, phosphate, or a combination of these rather than as the chloride salt, to avoid administering excessive chloride.

Sodium is lost due to the osmotic glucosuric diuresis and the absence of insulin essential for distal tubular sodium reabsorption. Since sodium losses are proportionally lower than water losses, the patient may present with hypernatremia. Since in the absence of insulin glucose is largely restricted to the extracellular space, an increase in its concentration causes water to flow out of the cells down an osmotic gradient into the ECF space, diluting the extracellular sodium. For each 100-mg/dL increment in plasma glucose above normal levels, the serum sodium concentration can be expected to decrease by 1.6 mEq/L, based on the analysis by Katz.³⁵ Recently Hillier and colleagues³⁶ demonstrated that the serum Na^+ will be decreased by 2.4 mEq/L for every 100-mg/dL increase in plasma glucose concentration. This correction factor brings the corrected Na^+ closer to the calculated Eosm than does the Katz correction, and its adoption is supported. Insulin has a direct antinatriuretic effect on the kidney. Following treatment with crystalloid solutions and insulin, significant edema (“insulin edema”) may develop. Occasionally, in patients with preexisting cardiovascular disease, frank congestive heart failure, pulmonary edema, or hypertension may be a consequence.⁶

Because the rapid anabolism of glucose may cause thiamine deficiency (Wernicke’s encephalopathy, beriberi) in patients with borderline thiamine stores, thiamine (100 mg) should be routinely administered. The B vitamins are critical cofactors in many intermediate metabolic reactions, and the catabolic state associated with uncontrolled diabetes predisposes to deficiencies; thus intravenous administration of B-vitamin preparations is prudent and advocated. HHS typically develops over days to weeks, during which time the patient is catabolic and may demonstrate many of the features of protein-calorie undernutrition. When malnourished patients are first given nutritional support, they may develop what has been called the “refeeding syndrome.”³⁷ This term describes the sequelae of rapid refeeding, and includes hypophosphatemia (with associated rhabdomyolysis, hemolysis, neurologic dysfunction, and muscle weakness), hypokalemia, hypomagnesemia (which may contribute more to the clinical syndrome than hypophosphatemia or hypokalemia), vitamin deficiency (especially thiamine), congestive heart failure, and benign refeeding edema (which may share pathogenetic features with insulin edema). This syndrome is well described in chronically malnourished patients (e.g., concentration camp victims), chronic alcoholics, and in anorexia nervosa, but also develops after as few as 7–10 days of hypermetabolic stress with inadequate nutritional support³⁸ (or its equivalent, the inability to anabolize nutrients). Uncontrolled diabetes, especially the hyperosmolar syndrome, and its subsequent treatment may be a common cause of the refeeding syndrome.³⁹ It may go unrecognized when only parts of the biochemical (e.g., hypokalemia, hypophosphatemia, hypomagnesemia) or clinical (e.g., insulin edema, muscle weakness) picture are present, but prophylaxis is prudent. A sample of potential pitfalls which may occur during treatment of HHS and an approach to their analysis are provided in Table 35-3.

COMPLICATIONS

Cerebral edema occurring in patients dying of otherwise uncomplicated DKA is well described.^{40–42} Most of the patients with this syndrome are young and have DKA rather than HHS, which runs counter to expectations. This complication accounts for at least 50% of DKA-associated deaths and over 30% of all deaths in dia-

TABLE 35-3. Potential Pitfalls During Therapy of Hyperglycemic Hyperosmolar Syndrome

Problem	Consider	Approach
1. Hypotension	(a) Myocardial infarct, sepsis, bleeding (b) Internal redistribution of fluid as hyperglycemia is corrected (c) Total body fluid depletion due to osmotic diuresis with inadequate volume replacement (d) Ongoing osmotic diuresis	(a) Std. work-up/specific therapy (b–d) Increase IV fluids
2. Worsening level of consciousness	(a) Meningitis, CVA, drugs, head trauma (b) Hypovolemia/hypoperfusion (c) Increasing Eosm (increasing SNa^+) (d) Cerebral edema (very rare in HHS) (e) Hypoglycemia (f) Wernicke's encephalopathy (refeeding syndrome) (g) $\downarrow\text{Mg}^{++}$	(a) Std. work-up/specific therapy (b) Increase IV fluids (c) Give hypotonic fluids (d) Mannitol IV/steroids IV/ $\downarrow$ insulin (e) Give glucose; reduce insulin (f) Thiamine/B-complex vitamins (g) Give Mg^{++}
3. Seizures	(a) CVA, prior seizure disorder, withdrawal, drugs, etc. (b) Early in HHS (seen in ~19%) (c) Cerebral edema (very rare in HHS) (d) $\downarrow\text{P}$, $\downarrow\text{Mg}^{++}$	(a) Std. work-up/specific therapy (avo diphenylhydantoin) (b) Insulin/hypotonic IV fluids (c) Mannitol IV/steroids IV/ $\downarrow$ insulin (d) Replace P, Mg^{++}
4. Tetany	(a) $\downarrow\text{Ca}^{++}$, $\downarrow\text{Mg}^{++}$ (b) P infusion (causing $\downarrow\text{Ca}^{++}$, Mg^{++}); rare when Mg^{++} is given routinely/proactively	(a) Replace Ca^{++} , Mg^{++} (b) Stop P; replace $\text{Ca}^{++}/\text{Mg}^{++}$ (c) Proactive Mg^{++} replacement
5. Muscle weakness (may be associated with respiratory failure)	(a) $\downarrow\text{K}^+$, $\downarrow\text{Mg}^{++}$, $\downarrow\text{P}$ (b) Rhabdomyolysis (commonly asymptomatic)	(a) Replace K^+ , Mg^{++} , P (b) Obtain creatine kinase (CK); if CK $>$ watch for ATN/renal failure and main high urine output (c) Respiratory failure may require mech ventilation
6. Cardiac/ECG abnormalities	(a) Peaked precordial T waves, prolonged PR, Vfib: $\uparrow\text{K}^+$ (b) Ectopy, tachyarrhythmias, (+)U waves, flat T waves: $\downarrow\text{K}^+$ (c) Wide QRS: $\downarrow\text{K}^+$, $\downarrow\text{Ca}^{++}$ (d) Short QT: $\uparrow\text{Ca}^{++}$ (e) Prolonged QT: $\downarrow\text{Ca}^{++}$, $\uparrow\text{Mg}^{++}$ (f) Vtach: $\uparrow\text{Mg}^{++}$ (g) Underlying heart disease (in presence of arrhythmias, CHF, etc.) (h) CVA (especially subarachnoid hemorrhage) with deeply inverted precordial T's. (i) ST segment elevation; friction rubs (underlying pericarditis vs. severe dehydration)	(a)–(f) Monitor ECG hourly, especially T Measure K^+ , Mg^{++} , Ca^{++} , correct necessary; routinely administer K^+ Mg^{++} unless levels are very high (g) Std. work-up/specific therapy (h) Std. work-up/specific therapy (i) If due to severe dehydration, especially DKA, will rapidly resolve with fluid rep
7. Persistent hyperglycemia	(a) Inadequate fluid infusion or oliguria (b) Renal failure (chronic or acute rhabdomyolysis) (c) Insulin resistance	(a) Increase fluids—hypotonic (b) May need to reduce fluids and increase insulin (c) Double insulin dose hourly
8. Persistent hyperosmolarity	(a) Persistent hyperglycemia (b) Hypernatremia—unmasked as glucose falls or excess Na^+ in infused isotonic solutions or inadequate free water replacement (c) Nephrogenic diabetes insipidus related to HHS (resistance to ADH)	(a) See 7 above (b) Increase IV fluids; use hypotonic electro solutions (c) Maintain high-volume hypotonic fluid in

TABLE 35-3. Potential Pitfalls During Therapy of Hyperglycemic Hyperosmolar Syndrome (Continued)

Problem	Consider	Approach
9. Oliguria	(a) Renal vascular occlusion or urinary obstruction or papillary necrosis (b) Chronic renal failure (CRF) (c) Acute renal failure (ARF) (d) Hypovolemia: Internal fluid redistribution as hyperglycemia is corrected, inadequate volume replacement, ongoing osmotic diuresis, or a combination of these (e) Rhabdomyolysis ($\uparrow\uparrow$ CK)	(a) Std. work-up/specific therapy (b) History; reduce IV fluids; use caution in volume replacement; $\uparrow$ dose of insulin (c) Std. work-up; if trial of increased volume infusion fails, treat as CRF (above) (d) Increase IV fluid replacement (e) Check K^+ , P , Mg^{++} and correct; adjust IV fluid volume to attempt to sustain high urine output
10. Edema	(a) Underlying cardiac, hepatic, renal, or GI disease (b) Excess Na^+ / H_2O administration (especially in elderly) (c) "Insulin edema"	(a) History/std. work-up/specific therapy (b) Restrict Na^+ and/or H_2O ; diuretics (c) If asymptomatic, recognize, reassure, and observe; if symptomatic or severe, give diuretics and restrict Na^+
11. Hyperchloremia	(a) Underlying renal disease; RTA (b) DKA with ketonuria resulting in Cl^- retention (c) Administration of excess Cl^- in treatment (e.g., use of $NaCl$ and KCl^- solutions)	(a) History/std. work-up/specific therapy (b) Use physiologic (hypotonic if associated with HHS) electrolyte solutions; avoid use of $NaCl$ and KCl (c) See (b) above. Use Plasmalyte, Isolyte, Normosol, lactated Ringer's, etc.; for K^+ replacement use K acetate/ K phosphate
12. Hypokalemia	(a) Typical of catabolic state of uncontrolled diabetes and unmasked as anabolism begins (b) Insulin (and refeeding syndrome) (c) Ongoing catabolism, osmotic diuretic losses and, in DKA, as cation accompanying ketoacids in urine (d) Hypomagnesemia (refractory hypokalemia) (e) Exogenous diuretic therapy (f) Bicarbonate administration	(a) Begin K^+ repletion at outset of therapy unless hyperkalemia, ECG changes, or renal failure present (b) Proactive and therapeutic K^+ replacement (c) Insulin plus K^+ (d) Replace K^+ plus Mg^{++} (e) History; stop diuretic; replace K^+ (f) Stop HCO_3^- ; replace K^+
13. Hypophosphatemia	(a) Catabolic depletion (b) Internal redistribution (insulin/glucose) (c) As part of refeeding syndrome [see (a) & (b) above] (d) If severe, may cause hemolysis	(a)–(c) Give P ; it is the necessary intracellular anion to enable K^+ and Mg^{++} to cross cell membranes and enter cell during anabolism; Cl^- does not cross cell membranes easily or facilitate translocation of K^+ and Mg^{++} to cell interior (d) Administer P
14. Hypomagnesemia	(a) Chronic catabolic deficiency state seen in $>50\%$ of poorly controlled diabetics (b) Osmotic diuretic loss (c) Internal redistribution (refeeding syndrome)	(a)–(c) Replace Mg^{++} ; it is a component of over 300 critical enzyme systems and of all energy generating systems in the body
15. Anemia	(a) Preexistent; may become manifest after rehydration (b) Hemolysis: (1) G-6-PD deficiency, (2) $\downarrow P$ (c) Bleeding; may see "coffee grounds" gastric contents in up to 25% of DKA/HHS	(a) Std. work-up/specific therapy (b) (1) Primarily seen in African-Americans and persons of Mediterranean descent (2) Measure P and replace; usually not seen unless P is <0.5 mg/dL (c) Std. work-up/specific treatment; hemorrhagic gastritis resolves with treatment; may require NGT drainage

TABLE 35-3. Potential Pitfalls During Therapy of Hyperglycemic Hyperosmolar Syndrome (Continued)

Problem	Consider	Approach
16. Thrombotic events	(a) Hyperviscosity, low flow, hypotension (b) Hypercoagulable state (seen in diabetes mellitus in general) not necessarily specific to HHS	(a) Rapid large-volume crystalloid infusions if necessary, Mg^{++} ; low-dose heparin prophylaxis (b) Consider anticoagulation as necessary, appropriate, and safe
17. Respiratory distress	(a) Pneumonia, CHF (b) Renal failure (c) Pneumothorax (iatrogenic due to central lines) (d) Pneumomediastinum or pneumothorax in DKA (e) ARDS (f) Rhabdomyolysis (g) $\downarrow P$, $\downarrow K^+$, $\downarrow Mg^{++}$ (h) Pulmonary embolism	(a) Std. work-up/specific therapy (b) History; reduce fluids if CRF and increase insulin; insulin may improve general circulatory and pulmonary fluid overload; redistribution of fluid to intracellular compartments (c) CXR; specific therapy (d) CXR; specific therapy (e) Central monitoring to exclude CHF or laryngeal overload; supportive therapy and ICU monitoring; prognosis poor (f) Check CK; supportive therapy (g) Monitor serum levels and replace as necessary (h) Std. work-up/specific therapy
18. Hypoxemia	(a) Pneumonia, pulmonary embolus, CHF (b) ARDS, especially with DKA (c) Pneumothorax, spontaneous in DKA	(a) Std. work-up/specific therapy (b) Poor prognosis; monitor with PCWP to differentiate from CHF; supportive care (c) CXR; specific therapy
19. Hypothermia	(a) Sepsis/infection (b) Hypoglycemia (c) DKA	(a) Std. work-up/specific therapy (b) Monitor plasma glucose, administer glucose (c) Poor prognostic sign in DKA
20. Abdominal pain	(a) Acute surgical abdomen (e.g., appendicitis, pancreatitis, cholecystitis, mesenteric ischemia) (b) Fatty liver (c) DKA	(a) Std. work-up/specific therapy (b) Monitor LFTs; hydration plus insulin usually resolves this problem (c) Especially in children may mimic acute surgical abdominal condition; rapidly responds to hydration and insulin
21. Hyperamylasemia/hyperlipasemia	(a) Pancreatitis, bowel infarction (b) DKA	(a) Std. work-up/specific therapy (b) Responds to hydration/insulin
22. Leukocytosis	(a) Sepsis (b) DKA	(a) Std. work-up/specific therapy (b) Resolves with hydration/insulin

betic patients under 20 years of age.⁴³ Asymptomatic cerebral edema and arterial hypoxemia have been reported in a number of young adults with DKA during routine therapy,⁴⁴ and subclinical brain swelling detected by CT occurs in children during the treatment of DKA.⁴⁵ Most adults^{44,46} and probably children⁴⁵ develop subclinical or "benign" cerebral edema⁶ during standard therapy for DKA. The majority of young patients with DKA have brain edema by CT scan on presentation prior to the initiation of any therapy.¹⁸ Most of these patients were not significantly hyperosmolar and none received hypotonic intravenous fluids, thus arguing against the osmotic gradient theory of the pathogenesis of cerebral edema. The overwhelming majority of diabetics who develop overt cerebral edema are young adults or children with DKA. The same is true of the rare patient with HHS who develops fatal cerebral edema. Indeed, only one such adult has been documented.⁴⁷ The

cerebral atrophy that accompanies the aging process may also accommodate excess cerebral water without significant damage.

An increasing number of pediatric patients are being encountered with HHS. Rother and Schwenk⁴⁸ identified 22 reported cases in infants and children between the ages of 6 weeks and 11 years. Most pediatricians treating patients with DKA recommend following the "corrected" sodium concentration as a guide to the speed of correction and the tonicity of the fluids used.

As many as 4000 persons die annually in the United States from DKA and HHS, whereas fatal cerebral edema is virtually unseen. It therefore becomes indefensible to base therapeutic recommendations on the prevention of this rarely encountered complication in light of the potential dire consequences of undertreatment, especially since no one has ever demonstrated that slower

correction of hyperosmolar hyperglycemia produces the desired benefit. Many more patients die because of undertreatment than from overtreatment of uncontrolled diabetes. Thus any recommendation that would reduce the rate of correction of hyperglycemia risks increasing the mortality rate and should be viewed with alarm.⁶

Other complications seen in HHS include thromboembolic events and possible disseminated intravascular coagulation, pulmonary aspiration of gastric contents in the presence of gastric stasis and obtundation, and the remarkably rare occurrence of renal failure and rhabdomyolysis.

Creatine kinase elevations of greater than 1000 IU/L have been described in over 25% of patients with HHS in the absence of stroke, myocardial infarction, or end-stage renal disease.⁴⁹ Thus subclinical rhabdomyolysis is not uncommon in HHS, but clinical manifestations are mild or absent.⁵⁰ The reason that acute tubular necrosis (ATN) and acute renal failure are uncommon despite the frequency of rhabdomyolysis, at times with very high CK levels, may be attributable to the high-volume osmotic diuresis that is the pathogenetic hallmark of HHS. Nevertheless, the presence of a CK greater than 1000 IU/L is associated with an increased mortality rate in HHS.⁴⁹

Pancreatitis⁵ is said to be a complication as well as an etiology of the hyperosmolar state. It has been suggested that hyperosmolarity may reduce blood flow to the pancreas, resulting in pancreatitis that becomes evident several days after admission. However, abdominal pain, leukocytosis, gastric stasis, vomiting, and an elevated amylase may all be secondary to uncontrolled diabetes, and renal impairment may also elevate the amylase. If such an entity does occur, it may be related to the vascular occlusions seen in some series^{21,22} or to the occasional marked hypertriglyceridemia seen in this setting. In this regard, marked hyperlipasemia with hyperamylasemia has uncommonly been reported⁵¹ in several hyperglycemic (>1000 mg/dL) hyperosmolar ketoacidotic patients, both with and without abdominal findings and without ultrasound and CT evidence of any pancreatic abnormality. Further, in these patients hyperamylasemia and hyperlipasemia were prolonged well after clinical recovery from HHS.

PROGNOSIS

The best prognostic indicator in uncontrolled diabetes is the age of the patient. Based on two large series of HHS,^{2,52} advanced age, a higher BUN, and a higher Na⁺ concentration are predictors of a poor outcome. In these series the mortality for HHS was 10–17%.

The availability of someone who is knowledgeable about the problems presented by the uncontrolled diabetic and facile in directing therapy is an essential element in improving the outcome of this metabolic emergency.

PREVENTION

Improvement in the outcome of this potential metabolic disaster requires an effective preventive strategy. Patients with HHS are elderly, have type 2 diabetes, and often live alone,⁶ and social isolation is a precipitant in 25–30% of episodes. The availability of a knowledgeable significant other (friend, neighbor, or family member) who maintains daily contact with the elderly diabetic is essential.² They should be educated to recognize alterations in the patient's

mental status and symptoms of loss of diabetic control, and to promptly report these to the physician. Public education about the presenting symptoms of diabetes will help reduce the one-quarter to one-third of patients who have HHS at presentation.

Residence in nursing homes predisposes to HHS,⁴ and nursing home residents are prone to develop dehydration and hyperosmolarity, so education of nursing home staff members in prevention and detection of this syndrome is essential. Prompt recognition and treatment of infections and the use of PneumovaxTM and annual influenza immunizations are important preventive measures in the elderly diabetic.

Providers should take into account the potential for medications prescribed for the elderly to cause or worsen glucose intolerance; aggressively apply home blood glucose monitoring in elderly diabetics; intensify efforts to improve blood glucose control; and reinforce education of patients and families regarding compliance with diet and hypoglycemic agents.

Host Defense and Infections in Diabetes Mellitus

Brian P. Currie

Joan I. Casey

GENERAL PROBLEM OF INFECTION IN DIABETIC PATIENTS

Literature reviews examining the association of infections with diabetes mellitus are often difficult to interpret and fraught with contradictions. A major contributory factor is that diabetes mellitus is a heterogeneous disease and so study populations need to be carefully identified in order to allow comparisons between studies (e.g., type 1 versus type 2 diabetes, well-controlled disease versus poorly controlled disease). In addition, diabetes mellitus is a relatively common disease, and as a consequence, anecdotal reports of various infections in diabetic patients can lead to spurious associations. Nonetheless, it is well established that certain infections occur almost exclusively in diabetic patients and that diabetic patients have a worse prognosis than nondiabetic patients after acquiring certain infections, such as acute pyelonephritis complicated by papillary necrosis or emphysematous pyelonephritis.^{1,2}

The morbidity and mortality associated with infectious diseases in diabetic patients are obvious in a study of patients admitted to an intensive care unit with diabetic ketoacidosis. Of the episodes of ketoacidosis, 28% were caused by infections. The mortality for the whole group was 6%, but in 43% of the patients who died, infection was considered the cause of death.³ Infection was considered the precipitating cause of ketoacidosis in 77% of patients admitted to hospitals in Dallas, Texas.⁴ While it is generally believed that diabetic patients with poor metabolic control have an increased susceptibility to infections, the previously mentioned studies indicate that in many cases the poor metabolic control may be the result of the infection, rather than the cause.

While antibiotics may be secondary only to insulin in increasing the life span of the diabetic patient, infection cannot be discounted now or in the foreseeable future as a major cause of morbidity and mortality among patients with diabetes. A knowledge of the normal host defense mechanisms and of those that are abnormal in the diabetic individual may be helpful in understanding the unusual predilection for certain infectious diseases among diabetic patients.

NORMAL HOST DEFENSE MECHANISMS

Skin

Normal skin is impenetrable to most bacteria, and infection rarely occurs unless the skin is damaged. The normal bacterial flora of the skin maintain an environment that is hostile to most pathogenic bacteria. The nerve supply of the skin is important in maintaining the integrity of the mechanical barrier by warning of potential injury from prolonged pressure or penetration by foreign bodies.

Blood Supply

Maintenance of normal nutrition and oxygen tension to tissues, as well as delivery of the humoral and cellular components of the immune system, is dependent on an adequate blood supply.

Humoral Immunity

The two major components of humoral immunity are antibodies and the complement system. Antibodies may neutralize the effect of bacteria, bacterial toxins, or viral capsids by combining with the organisms and preventing their attachment to cell surfaces. Other antibodies act by agglutinating organisms, thereby increasing clearance by the reticuloendothelial system, or by lysing bacteria. Opsonins, antibodies that may be specific or nonspecific, coat bacteria and enhance phagocytosis. Most of these reactions require or are enhanced by the action of complement, through either the classic or the alternate (properdin) pathway.

Phagocytic Function

This component of the immune response is mainly related to polymorphonuclear cells and macrophages. The latter cells are either wandering (alveolar, peritoneal, and skin macrophages and tissue histiocytes) or fixed to vascular endothelium in the liver, spleen, and lymph nodes. Various functions of phagocytes have been recognized, including random migration, chemotaxis and attachment, ingestion, and intracellular killing of bacteria. After ingestion of

bacteria by phagocytic cells, a vigorous burst of oxidative metabolism leads to the production of hydrogen peroxide, which combines with myeloperoxidase and halogen (iodide or chloride). This results in rapid killing of most pathogenic bacteria.

Lymphocytes

There is considerable information about the types and functions of lymphocytes and the substances elaborated by these cells when exposed to antigens or mitogens. There are at least three types of lymphocytes now recognized. These are the thymus-derived or T lymphocytes, the bone marrow-derived or B lymphocytes, and the non-B, non-T lymphocytes. The B cells can transform into antibody-secreting or plasma cells, whereas the T cells are regarded as the cells responsible for cell-mediated defense against viruses, fungi, and mycobacteria. T cells may help or suppress the immune functions of other cells such as the B lymphocytes, usually by the production of lymphokines.

ABNORMALITIES OF HOST DEFENSE IN DIABETES MELLITUS

Skin

Although the level of glucose in skin is directly related to that of the blood, there is no evidence that diabetic patients with skin infection have particularly high ratios of skin to blood glucose.⁵ Nasal and skin flora of diabetic patients have been studied frequently with varying results. Smith and coworkers¹ found that 53% of type 1 diabetic adults were nasal carriers of *Staphylococcus aureus* compared with 34% of nondiabetic adults and 35% of type 2 diabetic adults. Of diabetic children, 76% were nasal carriers compared with 44% of nondiabetic children. Tuzaon and associates also found a high rate of skin carriage of *S. aureus* in type 1 diabetic patients.¹ In contrast, Somerville and Lancaster-Smith did not find a high carriage rate for *S. aureus* in diabetic patients, but they unfortunately did not include nondiabetic controls.⁶ Peripheral neuropathy in diabetic patients can permit undetected disruption of the dermal barrier, which can serve as a portal of entry for pathogens. This decreased sense of touch prevents warning of potential injury from prolonged pressure or penetration injuries. In addition, once dermal barrier disruption occurs and infection is established, this decreased sense of touch contributes to delayed recognition and treatment (Table 36-1).

TABLE 36-1. Relationship of Host Defense Deficit to Disease Syndrome in Diabetic Patients

Host Defense Deficit	Disease Syndrome
Skin integrity	Erythrasma, cellulitis
Neuropathy	Infections secondary to trauma and ulceration; bladder infections
Blood supply	Peripheral vascular disease with ulcers, gangrene, and synergistic infections; invasion of vessels with bacteria and fungi resulting in malignant otitis or mucormycosis; possibility periodontal disease
Humoral immunity	Possibly bacterial infections due to <i>Pseudomonas</i> and group B <i>Streptococcus</i>

Blood Supply

Vascular problems in diabetic patients, secondary to both the microangiopathy of diabetes and the accelerated course of atherosclerosis in these patients, may predispose them to infection by disrupting normal nutrient and oxygen delivery, as well as disrupting normal immune function.

Recent evidence presented by Williamson and colleagues⁷ suggests that the hyperglycemia seen in poorly controlled diabetic subjects may result in an increased tissue cytosolic ratio of free NADH/NAD¹ (in spite of normal O₂ tensions) that mimics the effects of true hypoxia on vascular and neural function. Termed *pseudohypoxia*, the phenomenon is thought to play an important role in the pathogenesis of diabetic complications via a branching cascade of metabolic imbalances that can inflict injury on vascular tissue. Decreased adherence of polymorphonuclear cells and decreased diapedesis have been described in diabetic subjects, and there is evidence that this activity is a function of blood vessel endothelial cells, as well as of the polymorphonuclear cell itself.⁸ This oxidative stress contributes to disruption of normal vascular function and its potential impact on immune function.

In addition, poor metabolic control may result in increased vascular permeability, leading to increased diffusion of nutrients and edema formation.⁹ This provides an ideal milieu for proliferation of organisms, particularly streptococci.

Finally, a reduction in blood supply can translate into a reduction in delivery of antibiotics when treating established infections in diabetic patients. This could theoretically result in decreased efficacy and treatment failure. Seabrook and associates¹⁰ studied 16 diabetic patients receiving antibiotic and surgical therapy for foot infections and documented that the antibiotics administered in 9 patients provided no effective therapy against infection because of subtherapeutic tissue levels of antibiotic. Furthermore, adequate serum antibiotic levels did not guarantee therapeutic tissue antibiotic levels when tissue was sampled from postoperative viable tissue margins in these patients.

Humoral Immunity

Antibody production after exposure to a variety of bacterial antigens has been studied in diabetic patients. Decreased agglutinating antibodies to *Salmonella typhi*,¹¹ *Escherichia coli*,^{12,13} and *S. aureus*¹³ and decreased antitoxin antibodies to *S. aureus*¹⁴ and *Corynebacterium diphtheriae*¹³ have been reported in diabetics relative to nondiabetic persons. However, other studies, including those using pneumococcal polysaccharide, have shown that diabetic patients respond well to vaccines. Beam and coworkers¹⁵ studied 40 type 1 diabetic patients and 10 nondiabetic controls. They found that diabetic patients responded as quickly and as well as the controls. There was no correlation between antibody response and age, mean glucose concentration, or duration of diabetes.

Conflicting results have been reported when the bactericidal capacity of diabetic blood has been studied. Richardson¹¹ found defects in the killing of many bacterial pathogens, but Balch and colleagues¹² found no significant deficiency. The opsonic capacity of diabetic blood was also found to be impaired by Richardson.¹¹

Baker and associates¹⁶ studied opsonization of group B streptococci in neonates, type 1 diabetic patients, and healthy adults using type II group B streptococci. They found that inefficient bactericidal activity occurred among neonatal and diabetic sera com-

TABLE 36-2. Summary of Potential Leukocyte Dysfunction Reported Among Diabetic Patients

Neutrophils	↓ Leukocytosis ↓ Chemotaxis ↓ Phagocytosis ↓ Intracellular killing ↓ Metabolic burst
Lymphocytes	↓ Antibody function/opsonization ↓ Chemotactic factor ↓ Lymphokines

pared to normal sera. Only 6 of 15 diabetic patients had sera with efficient bactericidal activity for type II group B streptococci. While bactericidal activity was not dependent on the level of antibody, type-specific antibody did have the capacity to correct certain opsonophagocytic deficiencies.

The majority of studies of serum complement in diabetic patients have found normal or elevated levels so that impaired opsonic capacity of the blood is not necessarily related to deficient complement levels.^{11,12}

Phagocytic Function

Although opsonization was considered under humoral immunity, one should keep in mind that phagocytosis of bacteria cannot occur in the absence of opsonization except in unusual circumstances. Indeed, many of the problems in interpreting the inconsistent data relating to phagocytic function in diabetic patients may be due to the fact that there are so many separate steps in this process.

To begin with, random migration of leukocytes, which is probably the first step in the process of phagocytosis, has been reported to be abnormal in type 1 diabetic persons (Table 36-2).¹⁷ The ability of polymorphonuclear cells and macrophages to get to an area of infection also depends on their ability to adhere to and migrate through the endothelium of the capillary walls. As noted previously, this diapedesis of phagocytic cells could be dependent in part on the vessel wall. Migration and chemotaxis of cells have been tested by using the Rebuck skin window, and two studies have indicated a significant delay in response to skin abrasion in diabetic patients who were ketoacidotic. In the study of Perillie and coworkers, the defect was corrected in three of four patients by correction of the acidosis.¹⁸ Brayton and colleagues tested both ketoacidotic and nonketotic patients and found impaired responses in both groups.¹⁹ Bagdade and associates tested the adherence of polymorphonuclear cells from ten diabetic patients to nylon fiber columns and found it to be only 53% of normal. By lowering blood glucose levels of the patients, the defect was partly, but not fully corrected.²⁰ More recently, Anderson and associates⁸ examined neutrophil adherence to bovine aortic endothelial cells in 26 diabetic patients compared to age- and sex-matched healthy controls and found that a subset of 16 diabetic patients demonstrated highly significant decreases in basal adhesion. This study also indicated that an adherence-augmenting factor in diabetic plasma increased adherence of both diabetic and control neutrophils in the basal state. The adhesive effects of the factor were mediated through alterations in endothelium rather than neutrophils. Chemotaxis of polymorphonuclear cells from diabetic and nondiabetic subjects was studied by Donovan and coworkers²¹ using time-lapse microcinematography and video techniques, which revealed that diabetic cells move at normal rates. These authors collected cells for

these experiments by means of their adherence to glass coverslips. Since diabetic cells have poor adherence properties, this method of collecting cells could have resulted in the loss of those cells with poor chemotactic properties as well. There may be a mixed population of polymorphonuclear cells, some of which have normal adherence and chemotactic properties and others that do not. Other *in vitro* studies have been reported in which delayed chemotaxis was noted in both type 2²² and type 1 diabetic patients.^{17,22} In these studies, polymorphonuclear cells showed significantly decreased chemotaxis, and sera from diabetic patients were found to be deficient in chemotactic activity. These defects were unrelated to blood glucose levels, and although addition of insulin and glucose resulted in *in vitro* correction of the defect in two of the studies, chemotaxis was not improved in children given insulin.²² Molenaar and colleagues also found that chemotactic activity was significantly lower in polymorphonuclear cells of first-degree relatives of patients with type 1 diabetes mellitus when compared with other nondiabetic subjects.²³ McMullen and coworkers²⁴ found a positive correlation between a family history of diabetes and neutrophil chemotactic defects in 13 of 24 prediabetic subjects. These data suggest that the abnormality in chemotaxis may be intrinsic to the polymorphonuclear cell and possibly to the genetic makeup of the diabetic person.

Defects in phagocyte engulfment and intracellular killing of bacteria have been reported by several authors. In studies in which *S aureus* was used, ingestion of organisms was found to be normal in the diabetic patients, except for those with ketoacidosis.²⁵ Tan and associates²⁶ demonstrated impaired phagocytosis in 11 of 31, an intracellular killing defect in 3 of 31, and a combined defect in 3 of 31 diabetic patients using a *S aureus* challenge. There was no relationship between blood glucose levels and defects noted. Nolan and coworkers²⁷ found impaired engulfment and intracellular killing of *S aureus* among diabetic patients. Data from these latter studies suggest that improved control of blood glucose levels improves resistance to bacterial infections. Repine and colleagues²⁸ demonstrated that neutrophils from infected nondiabetic patients have an increased capacity to kill *S aureus* when compared to noninfected nondiabetic persons. Neutrophils from infected diabetic patients, however, failed to show this enhanced bactericidal capacity. This defect was seen in well controlled as well as in poorly controlled diabetic patients. They also noted that neutrophils from poorly controlled uninfected diabetic patients did not kill *S aureus* as well as those from well-controlled diabetic patients or nondiabetic persons. Impairment of ingestion of *Streptococcus pneumoniae* has also been reported, and this defect was partially corrected by improved metabolic control of the diabetes.²² In a later study, Bagdade and associates²⁹ suggested that the defect was related to serum factors, because it was partially corrected by serum from normal controls, whereas the diabetic serum caused impairment of phagocytic function in cells from nondiabetic controls. Crosby and Allison³⁰ were unable to demonstrate any impairment of ingestion of *S. pneumoniae* in diabetic patients who were not ketoacidotic.

Lymphocytes

Cell-mediated immunity, as measured by blast transformation of peripheral blood lymphocytes, has been measured in diabetic patients. When the mitogen phytohemagglutinin was used, the response of diabetic patients in good metabolic control was normal, whereas that of hyperglycemic patients was depressed.^{22,31} Impaired metabolism of glucose through the direct oxidative pathway

has been noted in lymphocytes from diabetic patients. The lymphocyte response to *Candida* antigen was reported to be normal in diabetic subjects;³² however, Plouffe and coworkers³³ found positive skin test reactions to *Candida* antigen in only 44% of diabetic patients compared to 88% of nondiabetic subjects. These authors also found the lymphocyte response to streptokinase-streptodornase to be impaired in diabetic subjects with poor glucose control and noted that this defect normalized with institution of metabolic control. When staphylococcal antigen was used in the blast transformation assay, the response of lymphocytes from both type 1 and type 2 diabetic subjects was less than that of nondiabetic subjects. This impaired response to staphylococcal antigen appeared to be unrelated to serum factors or metabolic control.^{34,35} Studies in streptozocin-induced and mutant diabetic animals demonstrate impairment of cell-mediated immunity by measurements of granuloma formation, intracellular killing of *Listeria monocytogenes*, and footpad swelling, all of which were less than normal in the diabetic animals.^{36,37}

Summary

Although the data are contradictory and inconclusive, there is strong evidence suggesting multiple immune defects in subsets of diabetic patients. As noted, much of the confusion is related to the fact that diabetes mellitus is a heterogeneous disease and that study populations have been poorly defined. The strongest evidence regarding an immune defect in diabetic patients is related to abnormalities of neutrophil function in patients with poor metabolic control (ketoacidosis or hyperglycemia). Studies using *in vitro* systems have documented impaired chemotactic responses and phagocytic activity of neutrophils in these subsets of diabetic patients. However, even among these patients the mechanisms of the defects have not been identified, and the clinical significance of impaired neutrophil function remains to be determined.

In addition, it has become clear that there is a complex interaction between polymorphonuclear cells, endothelial cells, and serum factors that control neutrophil function. Lack of control for these factors can also explain contradictory results.

SERIOUS INFECTIONS CAUSING MORBIDITY AND MORTALITY IN DIABETES MELLITUS

Although the entire immune system is probably alerted to defense against microbial invasion, certain defects may be more directly associated with certain types of infections. Some of the infections to which diabetic patients seem particularly vulnerable may well be related to some or all of the previously described defects, whereas others are still unexplained.

Skin and Soft Tissue Infections

Whether or not staphylococcal infections of the skin are more common in diabetic than nondiabetic persons is a controversy that has never been resolved. The increased skin and nasal carriage that is described in diabetic persons could lead to increased susceptibility to infection. Farrer and MacLeod³⁸ found staphylococcal infections to be twice as common among diabetic than nondiabetic patients who had other severe debilitating diseases. They also found more diabetic than nondiabetic patients among people admitted to hospitals with severe staphylococcal infections. A paper by

Williams³⁹ is frequently quoted as proof that skin infections caused by *S aureus* are not more common among diabetic than nondiabetic persons. In that paper, he describes 8 of 330 diabetic patients with boils and carbuncles and 166 nondiabetics with similar infections among 26,879 patients without diabetes. These data do not seem to justify the conclusion that staphylococcal skin infections occur no more frequently in diabetic than nondiabetic persons.

Candidal skin infections commonly occur in moist, warm areas around the breasts, thighs, and genitalia. This is especially common in diabetic patients who are overweight or who have been on antibiotics. These infections can cause extreme discomfort to the patient, and the resultant breakdown of skin may allow entry of *Candida* itself or more virulent organisms.

Diabetic foot infections account for at least one-quarter of all diabetic hospital admissions and are the most common cause of partial or complete foot amputations.⁴⁰ Most of these infections probably begin with soft tissue injury, which is unrecognized, secondary to peripheral neuropathy. Subsequent tissue edema, inflammation, and necrosis disrupt the dermal barrier and allow a portal of entry for infection. Concomitant peripheral vascular disease contributes to reduced healing and the onset of chronic infections. The resulting infected diabetic foot ulcer frequently involves deeper tissues, and a chronic underlying osteomyelitis can be established. The infections are characteristically polymicrobial and include aerobic gram-positive or gram-negative organisms coupled with microaerophilic and anaerobic organisms. Peptostreptococci can be recovered from 32–80% of diabetic foot ulcers, and *P magnus* is the most commonly isolated species.⁴¹ Krepel and coworkers⁴¹ demonstrated that 94% of *P magnus* isolated from diabetic foot ulcers produced collagenase, as opposed to 18% of isolates from intra-abdominal infections, and suggested that collagenase production from *P magnus* may be a significant pathogenic factor contributing to the establishment of infected diabetic foot ulcers.

Serious and often life-threatening infections of the skin and underlying tissues can occur when aerobic gram-positive (e.g., *S aureus* or streptococci) or gram-negative (e.g., Enterobacteriaceae or *Pseudomonas*) microorganisms act synergistically with microaerophilic or anaerobic gram-positive (e.g., peptococci or peptostreptococci) or gram-negative (eg, *Bacteroides*) microorganisms to produce necrotizing infections of the skin or underlying soft tissues. This syndrome is probably related to the neuropathy and peripheral vascular disease that allows minor infections to become established; the aerobic organisms consume the already compromised oxygen supply and allow anaerobic organisms to thrive. In this situation, the disease is frequently persistent and destructive. The initial presentation may range from that of an indolent ulcer to a fulminant infection, causing marked systemic toxicity and death.

Stone and Martin described 63 patients with necrotizing cellulitis of whom 47 were diabetic.⁴² The mortality rate was 85% for diabetic patients and 44% for nondiabetics. These patients presented with high fever, toxicity, and skin ulcers draining thin serosanguineous pus. Variable amounts of skin necrosis were noted, but gangrene was not necessarily extensive. Exquisite local tenderness inconsistent with the amount of skin involvement is characteristic. Subcutaneous gas may or may not be present. Infection of muscle and fascia is common, and necrosis of skin occurs as the underlying vessels become thrombosed.

These infections may begin in the perianal or pelvic regions, where anaerobic organisms are common, or in the extremities, where the vascular supply is compromised. Deep fascial planes of the neck may be infected from infected teeth or tonsils. The study

of Bessman and associates of polymicrobial abscesses in diabetic and nondiabetic mice demonstrated that these abscesses persisted for longer periods in diabetic mice.⁴³ Of added importance was their finding that enterococci were more synergistic for the growth of *B. fragilis* than of *E. coli*. In mixed infections, enterococci are sometimes regarded as nuisances rather than true pathogens, but this study clearly indicated that this is not the case. A variant of this disease, in which the synergistic organisms are usually all aerobes, has been called *necrotizing fasciitis* by some authors. This may lead to confusion because extensive involvement of skin, subcutaneous tissues, and deep fascia can occur in both syndromes and some authors use the terms interchangeably.^{42,44}

Bessman and Wagner described 48 diabetic patients with non-clostridial gas gangrene of the lower extremities.⁴⁵ Of the 83 organisms cultured from these patients, only three were anaerobic. Nonclostridial gas gangrene is much more common in the diabetic than is clostridial gas infection. It is important to make the distinction because the organisms are very different in their antibiotic sensitivities. *Clostridium perfringens* is sensitive to penicillin, whereas the anaerobes such as *Bacteroides* usually require metronidazole, clindamycin, cefoxitin, or possibly ticarcillin/clavulanic acid or imipenem. The Enterobacteriaceae may be sensitive to a variety of antibiotics such as aminoglycosides, third-generation cephalosporins, extended spectrum penicillins, or imipenem. Extensive surgical debridement is usually necessary and should be done early in the course of these infections.⁴²⁻⁴⁵

Goodman and coworkers⁴⁶ described risk factors for complications in 172 diabetic patients undergoing local operations for diabetic gangrene. Increased severity of infection, as measured by temperature, total white cell count, and subcutaneous gas, was associated with failure. During the 4.5 years of the study, improvement in outcome was achieved mainly with improvement in preoperative management of infection. The authors suggest delay of surgical procedures until medical control of infection has occurred. However, it should be emphasized that medical control must be accomplished as rapidly as possible, because extensive surgical debridement is usually necessary and should be done as early as possible in the course of these infections.⁴²⁻⁴⁵

Infections of the hands, although not as common as those of the lower extremities, nevertheless require comment because of the serious nature of the problem. Again, possibly because of the neuropathy and poor vision, the diabetic patient may be unaware of the onset of infection in the hand. Of 20 diabetic patients admitted to the hospital with hand infections, 6 required amputation to control infection and 1 because of impaired function of the extremity. Only 6 patients regained normal function. Most of these infections were synergistic.⁴⁷ Skin and soft tissue infections of diabetic persons are frequently complicated by osteomyelitis of contiguous bones.

Erythrasma is an unusual disease of the skin caused by *Corynebacterium minutissimum* (a gram-positive rod). In 19 patients with extensive erythrasma, 9 were known to be diabetic and 6 others had clinical evidence of diabetes.⁴⁸ As with many other infections to which the diabetic patient is predisposed, there is a predilection for this disease among alcoholic patients as well.

Malignant Otitis Externa

This disease is well named because associated mortality is over 50%. Over 90% of cases have occurred in diabetic patients over 35 years of age. Swimming and use of a hearing aid are additional predisposing factors. *Pseudomonas aeruginosa* is the usual infecting

agent and only rarely are other organisms involved. The presenting manifestations are those of chronic ear infection (i.e., pain and purulent drainage). However, the presence of tenderness and swelling of the surrounding tissues, and in particular polyps or granulation tissue in the floor of the external canal strongly suggest this diagnosis. The infection spreads via the clefts between cartilage and bone in the auditory canal to involve the deep soft tissues, parotid gland, the temporomandibular joint, the mastoid bone, and eventually the cranial nerves. Infection can also spread outward to involve the entire pinna. *P. aeruginosa* invades small vessels and produces an infectious vasculitis that compounds the microangiopathy of diabetes and makes this infection particularly virulent. The earliest neurologic complication is facial nerve palsy, and in these patients mortality is highest. Diagnosis is often delayed for 6–8 weeks because patients are misdiagnosed with noninvasive otitis externa. A high index of suspicion and early diagnosis are essential for successful treatment. Parenteral antibiotics (usually a beta-lactam with activity against *Pseudomonas* and an aminoglycoside), topical antipseudomonal ear drops, and surgical debridement are the mainstays of therapy.

Mucormycosis

This is another unusual but highly virulent infection that occurs most commonly in patients with diabetes, in particular those with ketoacidosis. The organism is the same ubiquitous gray-black mold as that found on bread and vegetables. The particular susceptibility of the diabetic for this infection may be related to the decreased leukocyte mobilization previously described and also noted by Sheldon and Bauer,⁴⁹ who infected diabetic rabbits with *Rhizopus* and *Mucor* species. Artis and colleagues⁵⁰ have shown that ketoacidotic sera from diabetic patients have poor iron-binding capacity. They suggest that the free iron enhances growth of *Rhizopus oryzae* and that this may be a mechanism for the increased susceptibility of ketotic diabetic subjects to this fungus. It is also noteworthy that this organism is capable of invading blood vessels, and the combination of factors found in diabetic hosts may explain why these patients are particularly vulnerable to this infection.

The organism probably first colonizes the nose or paranasal sinuses and spreads by direct extension to the orbit and surrounding tissues. Invasion of the cribriform plate and cranial cavity may occur rapidly. The clinical presentation is usually acute with periorbital pain, induration and discoloration of the lid, and bloody nasal discharge. Ischemic infarction of the lid and orbital contents may follow vessel invasion. Blindness and loss of sensation in the distribution of the ophthalmic division of the trigeminal nerve are diagnostic clues because these are unusual with other orbital infections. Black necrotic tissue may be seen in the nose or posterior hard palate. The internal jugular vein or the cavernous sinus may become thrombosed, and chemosis, proptosis, and retinal hemorrhage may occur.

Although this disease resembles malignant otitis externa in that blood vessels are invaded and progressive infection occurs, extension to the meninges and brain is more common in mucormycosis. Rarely the presentation of this disease is chronic. Morbidity and mortality from this infection are very high, and therapy may have to be started on the basis of clinical findings even in the absence of supporting laboratory evidence for mucormycosis. Biopsy of nasal turbinates or pharyngeal tissues must be done early for diagnostic purposes. Extensive surgical debridement is

necessary. Amphotericin is currently the only well-tested drug, and even with early and optimal therapy the disease is extensively disfiguring.

Oral Infections

The problem of periodontal disease in diabetic patients has received significant attention in the dental literature. It was found that this disorder was more common and more severe in diabetic than nondiabetic patients. Associated factors were the age of the patient, the duration of diabetes, the occurrence of complications, and the severity of hyperglycemia. In a study of patients with rapidly progressive periodontitis, 48% were found to have impaired leukotaxis. This leukotactic defect was also noted in alloxan-diabetic rats, and Lavine and coworkers suggest that decreased chemotactic factors or the altered basement membrane of the capillaries could account for the diminished accumulation of leukocytes and the increased numbers of anaerobic organisms found in the gingival crevice of these animals.⁵¹ Manouchehr-Pour and associates⁵² also demonstrated significantly reduced chemotactic responses of polymorphonuclear cells from diabetic patients with severe periodontal disease relative to cells from diabetic and nondiabetic subjects with mild periodontal disease or nondiabetic patients with severe periodontal disease.

Oral candidiasis is a well-recognized problem in diabetic patients. Carriage rate and density of *Candida albicans* in the mouth were higher in the diabetic than nondiabetic patients in a study with 50 persons in each group. Among the diabetic patients, no differences could be detected that correlated with degree of control, method of treatment, duration of disease, or age of the patients. Smoking and continuous use of dentures were associated with an increased prevalence of *Candida* colonization.⁵³

Gastrointestinal Infections

Telzak and coworkers⁵⁴ recently investigated the largest nosocomial food-borne outbreak of *Salmonella enteritidis* ever described in the United States and sought to determine host factors that increased the risk of infection after exposure to *S enteritidis* in a case control study. Cases consisted of 75 patients with stool culture-confirmed salmonellosis randomly selected from 274 patients with culture-confirmed disease, and controls consisted of 80 randomly selected asymptomatic culture-negative patients. Investigation of multiple potential risk factors indicated that diabetes (defined as a patient treated with insulin or an oral hypoglycemic agent) was the only independent risk factor identified for developing infection after exposure to a *Salmonella*-contaminated meal (odds ratio = 3.8, 95% confidence interval = 1.4, 10.5). When the case definition was restricted to culture-positive patients with symptomatic disease, diabetes remained a risk factor. While noting that diabetic patients may have granulocyte and T cell function abnormalities, the authors suggest that diabetes-associated decreased gastric acid production and decreased bowel motility may be contributory factors. Even more recently, an association between *Campylobacter* gastroenteritis and diabetes has also been described.⁵⁵

Additional studies are needed to corroborate these findings to determine if there is an increased risk of gastrointestinal infection for diabetic patients from other bacterial pathogens, and to deter-

mine if hyperglycemia is related to the risk and severity of these infections in patients with diabetes.

Urinary Tract Infections

The data relating to urinary tract infections in diabetic patients have been examined in two authoritative reviews which reached contradictory conclusions. Wheat states that the majority of controlled studies noted a two- to fourfold higher incidence of bacteriuria in diabetic women,⁵⁶ whereas Gocke and Grieco conclude that in well-controlled diabetes, urinary tract infections are no more likely in diabetics than in nondiabetic patients.²² Several studies support both views.^{57,58} In diabetic children, a prevalence rate similar to that of nondiabetic children is found, and the same appears to be true for diabetic men.⁵⁹⁻⁶¹ Among patients with hospital-acquired urinary tract infections, diabetic patients are more susceptible than nondiabetic patients.⁶²

Thus it appears that within populations in whom the prevalence of urinary tract infections is known to be high, the diabetic is even more likely than the nondiabetic to develop a urinary tract infection. Some of the reasons for this are that the diabetic patient may have a neurogenic bladder with urinary stasis, may be catheterized frequently, may have underlying renal disease, and may have impaired host defenses, all of which are predisposing factors for urinary tract infection. The diabetic leukocyte may be compromised by the hyperosmolar milieu in the renal medulla, which impairs phagocytosis even in the normal leukocyte.⁶³

There is universal agreement that urinary tract infections are more likely to cause serious complications for the diabetic patient than for others. Among bacteriuric pregnant women with diabetic retinopathy, a 50% perinatal death rate was found compared with 15% for women with microangiopathy without bacteriuria.⁵⁹ Studies done to localize the anatomic site of bacterial involvement in diabetic patients with asymptomatic bacteriuria document high rates of upper tract involvement. Ooi and colleagues found that 63% of diabetic women with asymptomatic bacteriuria had upper tract involvement, whereas Forland and associates found 80% of such patients had upper tract involvement.²² However, a prospective study suggested that asymptomatic bacteriuric diabetic women do not have an increased incidence of subsequent symptomatic urinary tract infection, including pyelonephritis.⁶⁴

Data suggest that diabetic patients may experience higher complication rates when they do develop renal infections. In a series of 52 patients with perinephric abscesses, 36 were diabetic. This diagnosis should be suspected in any diabetic patient who does not respond to adequate antibiotic therapy within 3 or 4 days. An abdominal or flank mass is a helpful diagnostic sign, but is present in only about 50% of cases. The organisms are usually those associated with urinary tract infections, although *S. aureus* can cause cortical abscesses by the hematogenous route. Although there are some data that these infections may respond to antibiotics alone, incision and drainage of the abscess are usually required.⁶⁵

A well-known, but now rather uncommon complication of urinary tract infection in diabetic patients is renal papillary necrosis. This disease is probably related to renal ischemia and is usually accompanied by rapidly deteriorating renal function, as well as fever, flank pain, and a poor response to antibiotic therapy. Obstructive uropathy or analgesic use may be concomi-

tant factors in the pathogenesis of this disease. Diagnosis is made by x-ray, and the retrograde pyelogram is preferred over the intravenous pyelogram in the diabetic patient with renal impairment.

Gas-forming infections of the kidney, renal pelvis, ureter, or bladder are uncommon, but not rare, and most occur in diabetic patients. The severity of this disease is related to the site of infection. When gas is confined to the collecting system, survival rates are much better than when the renal parenchyma is involved. Less severe disease can be managed with either antibiotic therapy alone or in conjunction with percutaneous drainage. Greater disease severity may warrant nephrectomy. Overall mortality approaches 18.8%.⁶⁶ As with the other renal complications, this disease should be suspected in any diabetic patient not responding quickly to appropriate antibiotics. Nausea, vomiting, and diarrhea in patients with urinary tract infections may give a clue to this disease. Tenderness, a palpable mass, or rarely, crepitus may be felt in the costovertebral angle. Diagnosis is made by abdominal CT scan, since plain radiographs identify gas in only one-third of patients.⁶⁵ The pathogenesis of this disease is obscure but is thought to be related to the ability of organisms such as *E coli* or *Klebsiella pneumoniae* to utilize glucose with subsequent formation of carbon dioxide and hydrogen. When infection with these organisms occurs in an area with vascular insufficiency, a severe necrotizing infection can occur. What is not clear is why it happens so infrequently, considering the frequent occurrence of urinary tract infections in diabetic patients with vascular disease and hyperglycemia.

Fungal infections of the urinary tract are not uncommon in diabetic patients. This may be a result of the use of antibiotics for bacterial infections and subsequent overgrowth of *Candida* species, or the fungus may spread from perineal candidal infection. The distinction between colonization and infection is often difficult to assess in these patients. Goldberg and coworkers suggested that patients who have *Candida* colony counts of greater than 10,000/mL in a clean-catch specimen should be catheterized, and if the count is still greater than 10,000/mL, the patient has actual urinary tract infection and not just colonization.⁶⁷ If infection is present in a diabetic patient, then treatment should be initiated. Oral fluconazole (200 mg the first day followed by 3–5 days of 100 mg/d) is highly efficacious in the treatment of *Candida albicans* cystitis. However, *C krusei* are routinely resistant to fluconazole. Alternatively, 5 days of continuous bladder irrigation of 50 mg of amphotericin in 1 liter of sterile water per day via a triple-lumen Foley catheter is reported to have resulted in cure rates of 70%. Oral flucytosine can be considered, but about 50% of candidal strains are resistant to this drug and bone marrow toxicity may occur in patients with renal impairment. Ketoconazole is poorly excreted in urine and should not be considered as a therapeutic option. Cases of candidal cystitis resistant to these treatment regimens may respond to low-dose intravenous amphotericin, but upper urinary tract disease or systemic infection should always be suspected in these cases and may require more extensive therapy.

Pneumonia

While hematogenous spread from sites of peripheral infection is one mechanism for development of pneumonia, the more usual route of infection is by inhalation of pathogenic organisms that colonize the oropharynx. The susceptibility of diabetic patients to *S aureus* and *K pneumoniae* pneumonias reported by Khurana and

coworkers⁶⁸ could be related to the increased nasal carriage of *S aureus* or oropharyngeal carriage of *K pneumoniae*. Patients with chronic illness appear to experience a change from the so-called normal oropharyngeal flora (i.e., from gram-positive organisms to gram-negative rods), and this could predispose patients to gram-negative rod pneumonia. Among alcoholics, 40% were found to be colonized with *K pneumoniae*,⁶⁹ and pneumonia with this organism is another disease that appears to be particularly common among alcoholic and diabetic subjects.

Phagocytosis by the pulmonary macrophage is the major defense mechanism against inhaled bacteria, and this may well be defective in the diabetic patient. Acidosis impairs the bactericidal mechanisms of the lung, and this could be an added factor in the uncontrolled diabetic patient.⁷⁰

Infections with either *S aureus* or aerobic gram-negative rods can produce severe, necrotizing pneumonias. Antibiotic therapy for 2–4 weeks is usually necessary and the mortality rate is 40–50%.

There is no documented evidence that pneumococcal pneumonia is more common in diabetic than nondiabetic hosts; nevertheless, the serious nature of this disease in any patient with chronic disease warrants the use of pneumococcal vaccine in these patients, especially those in the older age groups.

Emphysematous Cholecystitis

Although it is difficult to document an increased incidence of cholecystitis among diabetic patients, the more severe and fulminating infection with gas-producing organisms occurs frequently in diabetic patients. In 136 cases of emphysematous cholecystitis, diabetes mellitus was found in 38%. This disease differs from emphysematous pyelonephritis in that *C perfringens* is isolated in about one-half of the cases. In one series of 109 cases in which gall bladder bile was cultured, 95 were culture positive, with *Clostridia* spp isolated from 46% and *E coli* from 33%.

The clinical presentation of this disease resembles that of acute cholecystitis, but the outcome is radically different. Gall bladder perforation and gangrene are frequent, and the mortality rate is 3–10 times higher than in acute cholecystitis. The male to female ratio is about 3:1, the reverse of that seen in acute cholecystitis. Diabetic vascular disease is thought to be a factor in the pathogenesis of this unusual syndrome as it is with the other gas-forming infections. The diagnosis is made by finding radiographic evidence of gas in the gall bladder wall. Since the presence of gas may be seen in the first 48 hours of infection and spread to surrounding tissues in the next 48 hours, Wheat⁵⁶ suggests that diabetic patients with evidence of acute cholecystitis have abdominal x-rays each day for at least 4 days. This advice would seem particularly applicable if the patient is a diabetic male. Antibiotic coverage includes the triple combination of ampicillin (or an extended-spectrum penicillin such as piperacillin or mezlocillin), metronidazole, and an aminoglycoside. Imipenem may be useful for alternative antibiotic coverage because it is active against anaerobic bacteria, aerobic gram-negative rods, and *Enterococcus faecalis*. This drug does not have the nephro- or ototoxicity of the aminoglycosides, an important consideration in the diabetic patient. As with the other gas-forming infections, antibiotic coverage is useful only when used in association with early surgical therapy.

Bacteremia

While bloodstream invasion may result from infection with most bacterial pathogens, certain bacteria have been reported to pose a

particular threat to diabetic patients. These will be discussed in detail.

Staphylococcal Bacteremia

It has long been suggested that diabetic patients are predisposed to staphylococcal bacteremia, but this has never been established by controlled studies. Diabetes has been recognized as an underlying disease in 8–36% of patients with staphylococcal bacteremia, but studies designed to specifically evaluate the frequency of staphylococcal bacteremia in diabetic and nondiabetic patients have yet to be performed.¹ Although a number of studies have reported higher mortality rates associated with staphylococcal bacteremia in diabetic relative to nondiabetic patients, the most recent information suggests that there is no increased risk of mortality associated with these infections among diabetic patients. Cooper and Platt compared the presentation and course of 27 episodes of *S aureus* bacteremia in diabetic patients with 34 episodes in nondiabetic patients, and although they found no increased mortality in diabetic patients, when a primary focus of infection was present, they found diabetic patients were more likely to develop endocarditis than nondiabetic subjects.¹ It is possible that both granulocyte deficiencies and impaired cell-mediated immunity might be responsible for this increased severity of staphylococcal disease among diabetic patients.

Group B Streptococcal Bacteremia

Beta-hemolytic streptococci of the Lancefield group B have emerged as a leading cause of sepsis of neonates and pregnant women. However, in a population-based assessment of invasive disease due to group B streptococci, Farley and colleagues found that 68% of cases occurred among adult men and nonpregnant women.⁷¹ Of these patients, 31% were diabetic. This striking predilection for diabetic patients confirmed previous reports that noted the association between these two diseases.^{72,73} Bayer and associates⁷³ described 22 patients with bacteremic group B streptococcal infections, of whom 10 were diabetic patients. Pneumonia was the initial infection in five of these patients and cellulitis and pyelonephritis in two each.

The carriage rate of group B streptococci was studied in a group of diabetic compared to nondiabetic subjects.⁷⁴ No differences were found between the two groups. The studies by Baker and coworkers¹⁶ described above, showing inefficient opsonization of group B streptococci in diabetic patients, suggest at least one reason for these infections in diabetic patients.

The drug of choice for treatment of group B streptococcal infection is penicillin. The organism is less sensitive to penicillin than group A streptococci and therefore higher doses may be required. In a patient allergic to penicillin, sensitivities must be obtained from the laboratory because several of the strains are resistant to clindamycin, erythromycin, and tetracycline. Cephalosporins could be used, but there is a 10% risk of cross-reaction in cases of penicillin allergy.

Gram-Negative Rod Bacteremia

Bacteremia with aerobic gram-negative rods usually results from urinary tract infections, gastrointestinal disease, gallbladder disease, or in the hospitalized patient, intravenous catheters. In the diabetic patient, synergistic gangrene and gram-negative rod pneumonias are an additional hazard. Several studies document a high prevalence of diabetes among patients with gram-negative rod bacteremias. In their series of patients with *Proteus* bacteremia at the

Boston City Hospital, Adler and associates⁷⁵ found that 25% of the patients had diabetes. An investigation by Lewis and Fekety⁷⁶ of patients with gram-negative rod bacteremias at Johns Hopkins Hospital found that 20% of these patients had diabetes. The mortality rate among the diabetic patients was almost twice the overall mortality rate. Infection with gram-negative rods frequently requires the use of an aminoglycoside, and these antibiotics may be especially toxic in diabetic patients with compromised renal function. Dosage of these drugs should be carefully monitored, drug levels should be measured, and renal function tests should be done every day or every other day.

Tuberculosis

Whether there is an increased risk of primary tuberculosis after exposure for diabetic patients relative to nondiabetic patients has never been investigated, but diabetes and alcoholism have been suggested as potential risk factors for reactivation of latent tuberculosis.⁷⁷ Zack and coworkers⁷⁸ noted a 41% abnormal glucose tolerance rate among 256 nondiabetic patients hospitalized with tuberculosis. Unfortunately, long-term follow-up was not conducted, and the significance of this association remains obscure. Interestingly, a recent study comparing 5290 cases of tuberculosis to 37,366 controls diagnosed with deep venous thrombosis, pulmonary embolism, or acute appendicitis, identified diabetes mellitus as a risk factor for tuberculosis, especially among middle-aged Hispanics.⁷⁹ This association awaits further confirmation. Previous anecdotal reports describing a tendency for severe lower lobe tuberculosis in diabetic subjects have not been borne out.

Systemic Fungal Infections

Several fungal diseases that are uncommon in the general population seem to be more common in the diabetic population. Cryptococcosis is a disease caused by an encapsulated yeast that is inhaled. In the majority of cases, the host defenses of the lung are sufficient to prevent infection. In immunocompromised patients, pneumonia, meningitis, or disseminated disease may occur. Diabetes has been suggested to be a risk factor for cryptococcal infection, but this is not well established. Coccidioidomycosis, a fungal disease found in certain regions of California and Arizona, seems to be particularly virulent in people of certain genetic backgrounds, such as African-Americans or Asians. Baker and coworkers reported that the disease was particularly severe in patients with type 1 diabetes.⁸⁰ Rare cases of septic shock have been seen in patients with candidemia and diabetes.

SUMMARY

Despite advances in the knowledge of host defense in diabetes, there are numerous aspects of the complex host-pathogen interrelationship in diabetic subjects that remain unexplained. Why diabetic patients appear to have increased problems with pyogenic organisms such as *S aureus* and group B streptococci and not with common pathogens such as pneumococci has not been elucidated. Despite numerous unanswered questions, there is clear evidence of increased morbidity and mortality from infectious agents in the diabetic population. A knowledge of these problems coupled with

appropriate preventive and therapeutic measures may lessen the impact of these diseases in the diabetic host.

Diabetes and Surgery

Stephanie A. Amiel

K. George M. M. Alberti

The diabetic patient is not protected from the disorders that require surgical intervention in the nondiabetic population. Indeed the chronic complications of diabetes increase the likelihood of the need for surgery, with particular reference to cardiac and peripheral vascular and renal disease. It has been estimated in the past that a diabetic person has a 50% chance of having a surgical procedure during their lifetime.¹ This chance is steadily increasing with the greater life expectancy of diabetic people and the greater proportion undergoing angioplasty and coronary bypass operations.

Surgery in diabetic patients is complicated by the need for metabolic control during surgery itself and in the postoperative period when feeding is reinstated. The chronic complications are also likely to complicate recovery with particular respect to autonomic neuropathy, nephropathy, and macrovascular disease. A further challenge is offered by the greatly increased volume of (ambulatory) day surgery now performed, although it has been shown that diabetic patients are no more likely than nondiabetic patients to require full admission afterwards.² The ability to admit patients for stabilization preoperatively has also decreased.

Surgery and anesthesia have profound metabolic effects. These will be exacerbated in diabetes by insulin deficiency or hyposecretion and by insulin insensitivity (see Chap. 8). The poorly controlled diabetic patient will already be in a catabolic state, which will amplify the effects of surgery. There will be diminished phagocyte function with impaired resistance to infection and delayed wound healing. Together with the chronic complications of diabetes, these factors will add to the morbidity and mortality of the surgical procedures themselves. The aim of treatment of the diabetic patient undergoing surgery must therefore be to control the metabolic scenario in such a way that the risks are no greater and the outcome no worse than for the nondiabetic person.

In the remainder of this chapter, the metabolic effects of surgery and anesthesia will be briefly reviewed together with the impact of diabetes on these events. The pre-operative assessment of the diabetic patient, anesthetic management, and peri- and postoperative treatment will then be discussed, together with the management of diabetes in certain special situations such as emergency surgery and cardiopulmonary bypass. For more details the reader is referred to several recent reviews.³⁻⁹

METABOLIC EFFECTS OF ANESTHESIA AND SURGERY IN THE NORMAL AND DIABETIC STATES

Under normal conditions, metabolic homeostasis is maintained by a fine balance between the anabolic hormone insulin and the

major catabolic hormones, glucagon, the catecholamines, cortisol, and to some extent, growth hormone (see Chap. 1). In the fed state the anabolic actions of insulin predominate, with the stimulation of processes leading to fuel storage: glycogenesis, lipogenesis, glycolysis (to promote new fatty acid synthesis in the liver), and protein synthesis.

In starvation the balance is tilted towards catabolism; insulin concentrations fall while those of the catabolic hormones stay the same or rise slightly. There is enhanced production of the oxidizable substrates, glucose, fatty acids, and ketone bodies through stimulation of glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis, which together with increased proteolysis provide gluconeogenic substrates. Insulin plays a key role in restraining these events through its important anticatabolic actions, as they respond to small amounts of insulin and thereby allow controlled release of substrates. These processes become disturbed in stress states such as surgery, particularly if diabetes is superimposed.

Anesthesia

The impact of modern anesthetic agents on metabolic control is relatively small. Epidural anesthesia blocks catecholamine release and can reduce postoperative protein catabolism (see reference 8). In one study, isoflurane was associated with a greater increase in plasma glucose than fentanyl/midazolam with only the former causing increased hepatic glucose production. Nonetheless the effects are relatively small and disappear rapidly postoperatively.¹⁰ Both locoregional and general anesthesia can be used safely. More important is the presence of autonomic neuropathy or cardiovascular disease in the patient.

Surgery

Surgery induces a trauma-like stress state⁹ and provides a classic hyperglycemic challenge. The stress response to both the condition for which the surgery is being performed and any associated anxiety includes adrenergic and sympathetic activation and elevations of circulating catecholamines, cortisol, and growth hormone. These may be sufficient to convert well-controlled diabetes into hyperglycemia—even ketoacidosis—particularly when the surgical condition is an acute one. Furthermore, immobility reduces muscle consumption of glucose and confinement to bed causes insulin resistance, contributing to the tendency toward hyperglycemia. Surgery is associated with a reduction in insulin sensitivity that persists for 3 weeks.¹¹ Using the short insulin-tolerance test, a 50% fall of insulin sensitivity has been demonstrated 24 hours after laparoscopic cholecystectomy.¹² Thorell and associates showed a one-

third decrease in sensitivity even after inguinal hernia repair and a 56% decrease after cholecystectomy.¹³

Food deprivation further worsens the catabolic state. In health the small amounts of circulating insulin still present limit the extent of the catabolic processes. Interestingly, it is possible to normalize postoperative insulin sensitivity by perioperative insulin and glucose infusion¹⁴ and to attenuate it with preoperative glucose loading orally or intravenously.¹⁵ In surgery as opposed to starvation, it is noteworthy that the catabolic processes do not result in elevated circulating levels of plasma free fatty acids or ketones, so the body loses the protein-sparing effect of these metabolic fuels and proteolysis continues unabated. This is probably due in part to the elevated insulin levels which are found due to insulin resistance.

Classical stress hormone responses are unlikely to be the sole or perhaps even major cause of surgery-related insulin resistance. A study of healthy subjects undergoing elective surgery found a significant fall in whole-body insulin sensitivity on the first postoperative day to be strongly correlated with elevated levels of the cytokine interleukin-6.¹⁶ Other cytokines did not show this pattern, perhaps because of the relatively limited tissue damage associated with these procedures. It is noteworthy that in a small number of patients, the insulin resistance persisted to at least the fifth postoperative day. Cholecystectomy had notably more effect on insulin sensitivity, stress hormones and IL-6 levels than herniorrhaphy, which was not associated with a significant increase in stress hormones by day one.

The molecular mechanisms of the insulin resistance of surgery remain to be elucidated, but a major effect on peripheral glucose utilization has been observed with reductions in glucose transport, nonoxidative glucose disposal and intracellular glycogen synthase demonstrated in muscle tissue sampled on the first postoperative day.¹⁷ It is likely that impaired translocation of the glucose transporter GLUT-4 in response to insulin in muscle is an important mechanism.

Neural effects are also important in the catabolic response. Epidural anesthesia, spinal blocks, and splanchnic nerve block have all been shown to ameliorate the endocrine and metabolic response.¹⁸

Diabetes

The uncontrolled diabetic patient will already be in a catabolic state. Superimposition of the metabolic stress of surgery will result in a major worsening of this state. Severe hyperglycemia leads to an osmotic diuresis, with loss of salt and water. In extremes, dehydration and hypovolemia may ensue. Hyperglycemia is associated with decreased levels of antioxidants, disturbances of coagulation, including increments in fibrinogen and plasminogen activator inhibitor (PAI-1), and interferes with neutrophil function. Ketosis with severe acidemia may also ensue.

Not surprisingly, few data are available on the absence of treatment of diabetes during surgery. Blood glucose levels have been shown to rise from about 180 mg/dL (10 mmol/L) to about 270 mg/dL (15 mmol/L) postoperatively with ketone body levels rising to about twice the level of nondiabetic controls.¹⁹ The situation is similar metabolically even in patients with type 2 diabetes mellitus (T2DM) undergoing minor surgery that generates a relatively small stress response. Blood glucose levels were again greater than in the nondiabetic, reaching only 180 mg/dL (10 mmol/L). Ketone body and fatty acid levels were also above normal, although not at a dangerous level.²⁰

In order to minimize the adverse effects of these metabolic events on the diabetic patient, meticulous attention to metabolic control is required. The response of surgery relates to the severity of the surgery. Patients with type 1 diabetes mellitus (T1DM) will require insulin replacement regardless, but T2DM patients will probably be able to mount an adequate insulin response to minor surgery and insulin therapy may not be required. By contrast, they should receive insulin for major surgery.

Aims of Therapy

The main aim of therapy must be to avoid any excess morbidity and mortality when compared with the nondiabetic population. To achieve this, hypoglycemia, excessive hyperglycemia, increased protein catabolism, and undue electrolyte disturbances should be prevented. In addition, attention should be paid to cardiovascular status and to problems created by the long-term complications of diabetes. These goals are best achieved by controlling the metabolic status of the patient. There is still argument, however, as to how stringent metabolic control should be. The diabetologist may seek to attain normoglycemia, but this has potential dangers in the unconscious patient. In general, it is probably wiser to aim for blood glucose levels at which resistance to infection and phagocyte function are not impaired and at which normal wound healing can take place. The threshold for these effects is probably around 200 mg/dL (11 mmol/L) so the target for glycemia is in the range of 120–180 mg/dL (6.7–10 mmol/L) during the operative period.

Preoperative Management

All patients require a full preoperative assessment. The diabetic patient presenting for surgery is more likely to have comorbidity than the patient without diabetes. In the young person with a relatively short duration of diabetes, the main focus of attention will be glycemic control, but in the older patient with a longer history of diabetes, careful assessment of the possible chronic complications is necessary if the patient is to be well managed perioperatively.

Assessment of glycemic control and current therapeutic regimen is mandatory. The glycated hemoglobin will indicate the patient's habitual control. The random glucose is not useful until the time of starting the peri-operative management.

Cardiovascular status should be assessed by history and resting ECG. Asymptomatic angina is reported in diabetic patients, but a stress test such as an exercise ECG or thallium scan is not routinely indicated. Symptomatic autonomic neuropathy is fortunately uncommon in diabetes, but lesser degrees of cardiac denervation are not. The anesthetist should be aware of potential defects in the normal cardiovascular responses to hypotension in anesthesia induction. A report of an exaggerated pressor response to intubation has been published²¹ in ten consecutive patients presenting for vitreous surgery. All had some degree of autonomic dysfunction preoperatively and all failed to show a heart rate increase when blood pressure fell. This is particularly important, because cardiorespiratory arrest is known to occur in patients with autonomic neuropathy and diabetic patients are more likely to have respiratory arrests postoperatively.²²

Hypertension coexisting with diabetes is common and its management should be optimized prior to surgery. Peripheral vascular disease should be sought by routine palpation of pedal pulses and peripheral neuropathy by history and the patient's inability to sense pinprick, light touch, and temperature and vibration stimuli. The

patient with nonpalpable pedal pulses, especially if the feet are insensitive, is very vulnerable to pressure ulceration and contact with bed frames or adjacent radiators must be prevented, as must prolonged contact of the heels with unyielding mattresses. Heel ulceration resulting from compression of the skin over the heel between bone and bed is common in badly managed surgical patients and preventable by proper care.

Retinal status is unlikely to be adversely affected by surgery, although retinal hemorrhage may be precipitated by sudden hypertension or hypoglycemia and sudden tightening of glycemic control may be associated with worsening of retinal status, which should be documented preoperatively and referred for treatment if preproliferative or proliferative.

Renal impairment is a common problem in long duration diabetes and renal status must be assessed preoperatively.

Careful assessment of metabolic status is essential. In T1DM patients, every effort should be made to achieve good glycemic control before admission. Patients should be on short- and intermediate-acting insulins. In T2DM patients, chlorpropamide should be stopped, as should glyburide in the elderly, because of risk of hypoglycemia, and short-acting agents substituted. Metformin should be stopped on the day of operation except in those with abnormal renal function, in whom it should be stopped without delay.

All these measures (Table 37-1) should be undertaken preadmission. Ideally, patients should be admitted one or two days before surgery to allow final assessment. This often does not occur, however, making preadmission screening even more important. It is worth noting that diabetes may be diagnosed for the first time when a patient is admitted for routine surgery. This is particularly true for elderly patients, and T2DM is usually the diagnosis. Operation should be delayed until glycemic control has been achieved and the patient fully assessed. In general, one should aim for fasting glucose levels of <125 mg/dL (7 mmol/L) and postprandial levels of <180 mg/dL (10 mmol/L). For urgent surgery (e.g., for malignant disease), control can be rapidly established in the hospi-

tal in a few days with insulin therapy. In less urgent situations, time can be taken to establish control conventionally with diet, exercise, and oral hypoglycemic agents.

Ideally pre- and postoperative care should be under the joint management of the diabetes, anesthetic, and surgical teams.

Perioperative Management

In T1DM patients, the need for continued insulin replacement is self-evident. In T2DM patients the indications are also clear. In a patient well controlled on diet alone, management may be possible, especially for minor procedures, as with nondiabetic patients, with the exception that blood glucose should be monitored preoperatively and hourly thereafter, and insulin replacement should be instituted if glucose levels rise above 11 mmol/L. With all other diabetic patients on any form of pharmacologic therapy to lower blood glucose, replacement of that therapy with monitored intravenous insulin therapy is mandatory.

Ambulatory surgery offers special challenges, but is best avoided except in well-controlled T2DM patients. Operations under local anesthetic, such as for cataracts, can then safely be undertaken with omission of therapy on the morning of the operation. It has been shown that cataract operations under local anesthesia cause relatively minor hormonal and metabolic disturbance compared with general anesthesia.^{2,3}

Blood Glucose Control

A glycemic target should be determined for each patient. The ideal is normoglycemia (venous plasma glucose between 70 mg/dL [4 mmol/L] and 125 mg/dL [7 mmol/L]), but the risk of hypoglycemia is a concern. The classic signs of hypoglycemia may be masked by anesthesia and may in any case be absent in patients with longstanding diabetes taking insulin. A modified goal of 120–200 mg/dL (6.7–11 mmol/L) is acceptable during surgery and can then be tightened up postoperatively. This will keep glucose levels below those which cause glycosuria and dehydration and will not inhibit phagocyte function and wound healing.

Blood glucose can now be measured reasonably accurately at the bedside and in the operating suite with test strips and a meter, or electrochemically or using a microcuvette. However, it is vital that such machines are calibrated on a regular basis. Blood glucose should be measured on the morning of surgery, every 2 hours until the patient is anesthetized, hourly during surgery, and then every 1–4 hours during the first 24 hours, depending on the seriousness of the procedure.

T1DM Patients

All T1DM patients should be treated with insulin during surgery involving general anesthesia, regardless of the seriousness of the operation (Table 37-2). Operations should be scheduled early in the day, primarily because of the potential need for laboratory services for postoperative monitoring.

Insulin Therapy

Over the years, a variety of different regimens have been advocated for glycemic management during surgery. These have ranged from giving no insulin at all to using a low-dose SC insulin infusion with no added glucose. The former has obvious unwanted catabolic sequelae (see above), while the latter was only safe because patients were hyperglycemic preoperatively and therefore did not become hypoglycemic.

TABLE 37-1. Preoperative Assessment and Preparation of the Diabetic Patient for Surgery

General Measures

- Cardiovascular assessment
 - History of angina, infarction
 - History of hypertension
 - ECG
 - Blood pressure
 - Full examination including peripheral pulses

Neurologic assessment

- Peripheral neuropathy
 - Autonomic examination: R-R interval

Renal assessment

- Proteinuria
- Serum creatinine
- Urine culture
- Electrolytes (sodium, potassium)

Metabolic Assessment

- Glucosylated hemoglobin
- Home glucose control
 - T1DM: Stop long-acting insulin, substitute BID split and mixed or TID regimens.*
 - T2DM: Stop long-acting sulfonylureas (e.g., chlorpropamide). Substitute short-acting agents. Stop metformin on day of surgery.

*For day surgery, omit or use half the dose of intermediate-acting insulin the evening before surgery.

TABLE 37-2. Outline Guide to Management of Diabetes During Surgery

	Diet	Oral agents	Insulin
Minor surgery	Check BG preop. If <200 mg/dL, continue. If >200 mg/dL, start GIK.	Check BG preop. If <200 mg/dL, continue. If >200 mg/dL, start GIK. Omit on day of surgery until first meal.	Check BG preop. If <270 mg/dL, continue. If >270 mg/dL, stabilize on insulin infusion until BG <200 mg/dL and/or delay operation.
Major surgery	Use GIK as for T1DM. If BG >270 mg/dL, stabi- lize on insulin infusion until BG <200 mg/dL and/or delay operation.	Use GIK as for T1DM. If BG >270 mg/dL, stabi- lize on insulin infusion until BG <200 mg/dL and/or delay operation. Omit sulfonylureas.	As above.

For GIK patients, monitor BG preoperatively, intraoperatively (if operation >2 h), immediately postoperatively, then every 2 hours until BG stable. For others, check BG pre- and postoperatively. Use test strips + meter for BG monitoring (see text for precautions). GIK: glucose-insulin-potassium or insulin (pump) + glucose:potassium infusion.

The most widely used recommendations, however, are variants on two themes: (1) SC insulin with IV dextrose; and (2) IV infusion of glucose and insulin either separately or together, generally with added potassium.

Subcutaneous Regimens

Several SC regimens are still recommended for use during surgery.²⁴ SC regimens allow little flexibility and the rate of absorption, which is always variable, may be further compromised by changes in circulation and peripheral perfusion induced by anesthesia. There seems little rationale for their continued use. In a summary of studies several years ago,²⁵ we showed that plasma glucose levels 0–1 hour postoperatively with subcutaneous regimens ranged widely, between 193–390 mg/dL (10.2–21.7 mmol/L) and 155–310 mg/dL (8.5–17.2 mmol/L) at 4 hours, compared with a mean of 189 mg/dL (10.5 mmol/L) and 186 mg/dL (10.3 mmol/L), respectively, when intravenous insulin regimens were used. Better outcomes have been reported in cardiac surgical patients using IV infusion of insulin compared with SC insulin.²⁶ The only exception may be day surgery under local anesthesia.

Intravenous (IV) Regimens

A variety of different routines have been proposed for the use of IV insulin. Some use a fixed infusion rate of insulin, modifying the glucose infusion according to blood glucose levels, whereas the converse method of keeping glucose infusion constant and varying the insulin infusion rate has also been suggested. Others have varied the initial insulin dose according either to preoperative blood glucose level or to previous insulin dose. Another group has devised a series of complex algorithms to determine the rate of insulin administration. We have summarized these different options previously.²⁷ There is still some support for the use of hourly IV boluses when pumps are not available.²⁸ This does not seem logical or necessary and has been tested primarily in T2DM patients.

Two main variants of insulin infusion protocols are now recommended. These are: (1) combined insulin and glucose infusions with added potassium (GIK); and (2) insulin given by infusion pump with glucose (and potassium) given by separate infusion (IP/GK). In both cases potassium is necessary as insulin infusion lowers plasma potassium levels. Both regimens have their advantages, with GIK being safest, but both methods utilizing

separate infusions are the gold standard for well-equipped, well-staffed centers.

Glucose, Insulin, and Potassium (GIK) Regimen This system was originally designed for use in average general hospitals and needed to be simple, safe, and reproducible. Safety is ensured by glucose and insulin being in the same infusion so that their rates of infusion will be synchronously variable. It remains in use today essentially as it was first described in 1979.²⁹ The infusate comprises 10 units regular insulin plus 10 mmol potassium chloride (KCl) in 500 mL 10% dextrose given at 100 mL/h. Interestingly, this was not markedly different from a suggestion made by Galloway and Shuman in 1963.²⁹ Based on the original data, we subsequently increased the content of insulin to 16 units, giving 0.32 U/g glucose. Since the advent of U100 insulin, this has been modified to 15 units (0.30 U/g glucose). In one study, plasma glucose levels remained within the target range in 82% of cases and unexplained hypoglycemia and severe hyperglycemia were avoided.³⁰ Few comparative studies have been made, although unequivocally better metabolic control has been shown than with SC insulin.³¹ The amount of insulin required varies to some extent, depending on the state of the patient and preexisting conditions. Table 37-3 shows amounts of insulin required in different states. These can be used as starting doses.

Some have recommended the use of 5% rather than 10% dextrose. We prefer the latter because it gives 240 g carbohydrate (960 kcal) per 24 hours, rather than 120 g (480 kcal). It has been suggested that at least 150 g carbohydrate per day plus insulin is needed to inhibit hepatic glucose production and protein catabolism,³² although this is somewhat arbitrary. Slower rates of administration of more concentrated solutions of glucose are appropriate

TABLE 37-3. Insulin Requirements During Surgery

Condition	Insulin (U)/Glucose (g)
Normal weight	0.25–0.35
Obesity	0.4
Liver disease	0.4–0.6
Steroid therapy	0.4–0.5
Sepsis	0.5–0.7
Cardiopulmonary bypass	0.9–1.2

when it is necessary to restrict fluid administration or when complex fluid replacement regimens are needed for other reasons. Thus 50 mL/h of 20% dextrose or 20 mL/h of 50% dextrose may be used, given through a central line.

There are some disadvantages to the GIK regimen. These include the need to change the whole infusate bag if a change of insulin dose is needed, although this is surprisingly infrequent for routine operations. More important perhaps is that insulin is absorbed into the material that makes up IV fluid bags and infusion sets. The problem can be diminished by flushing the infusate through the infusion set. It is not a major problem in practice, but is avoided by using a more concentrated insulin solution in a syringe pump.

Separate Insulin and Glucose Regimens Many centers, particularly in the U.S., prefer to give insulin separately using an infusion pump following the groundbreaking study of Taitelman and associates.³³ This method certainly assures more precise delivery of insulin and allows speedy change of dose or infusion rate as required. It has also been used extremely effectively in children and adolescents.³⁴ It is probably the gold standard because of its flexibility, but if it is not carefully monitored, there is a risk of giving glucose without insulin and vice versa. The same dosages of units of insulin per gram of glucose as those above also apply to this method. Interestingly, in one study, separate infusions were preferred by the nursing staff and attained marginally better glycemic control than the GIK method.³⁵

Practical Guidelines

Blood glucose and potassium should be checked on the morning of surgery. Glucose can be measured with a test strip and meter, but it is axiomatic that this should be done only by properly trained staff. A simultaneous sample should be sent to the laboratory as a later check. If blood glucose is greater than 270 mg/dL (15 mmol/L), surgery should be delayed, particularly if major surgery is planned. Either an attempt can be made to achieve control rapidly using the GIK infusion with twice the usual insulin content (60 U/L 10% glucose) or surgery may be delayed. Alternatively, insulin can be given at 4–6 U/h by syringe pump. If blood glucose is greater than 400 mg/dL (22.2 mmol/L), then delay and restabilization are mandatory.

The intravenous insulin and glucose infusion can be started when the surgical patient is due for his or her first insulin dose after being made NPO. The patient scheduled for morning surgery who is normally controlled on intermittent insulin injection therapy does not need to start intravenous insulin (with its requirements for hourly blood glucose monitoring) until just before breakfast the day of the procedure, despite stopping eating after the evening meal the day before. This allows the patient a near-normal night's sleep. It is sensible to check the blood glucose at bedtime and at 3.00 AM, as these are the times when the action of the evening's subcutaneous regular and intermediate-acting insulins, respectively, will be waning. Supplemental subcutaneous regular insulin (25–50% of the patient's usual premeal doses) can be prescribed for these times if the blood glucose is over 11 mmol/L, to avoid starting the intravenous insulin in a very hyperglycemic state. Similarly, the patient scheduled for afternoon surgery can be given a light breakfast with a suitably adjusted dose of regular insulin and intravenous insulinization started midmorning.

The GIK regimen can be based on either 10% (preferably) or 5% dextrose (Table 37-4). Careful monitoring of the plasma glu-

TABLE 37-4. Glucose-Insulin-Potassium (GIK) Infusion Protocol

Plasma Glucose mg/dL	Insulin dose (U/L)	
	Protocol A	Protocol B
<80	↓ 10	↓
<120	↓ 5	↓
120–180	Leave unchanged	
>180	↑ 5	↑
>270	↑ 10	↑

A. 30 U regular insulin (human) + 20 mmol KCl in 1000 mL 20% dextrose. Infuse at 100 mL/h.

B. 15 U regular insulin (human) + 20 mmol KCl in 100 mL 5% dextrose. Infuse at 100 mL/h.

cose is key. The first check after the fasting sample should be 2 hours or immediately preoperatively, whichever is first. Plasma glucose and potassium are measured again in the recovery and intraoperatively if it is a long operation.

For the insulin pump regimen, it is usual to make a solution of regular insulin in saline or Gelofusin of 1 unit per mL, by putting 50 units of the insulin in a 50-mL syringe and making the total volume of solution 50 mL by adding the diluent. This means the pump setting, in mL/h, is numerically the same as the number of units per hour prescribed. More dilute solutions can be made for very insulin-sensitive subjects or children. The dextrose is given in the GIK regimen—preferably 10% solutions at 50–100 mL/h, each liter containing 20 mmol potassium. The insulin infusion rate is set at slightly less than the patient's usual hourly requirement (total daily subcutaneous insulin doses divided by 24, or 2 U/kg for adults if the daily dose is not known) for the target plasma glucose level of 120–180 mg/dL, and adjusted up or down according to the plasma glucose measurements made at the bedside (Table 37-4). The scale should be reviewed regularly and adjusted to maintain plasma glucose in the range of 120–180 mg/dL.

T2DM Patients

All patients left on their usual hypoglycemic drugs risk hypoglycemia in response to the stress of surgery and hypoglycemia in response to the lack of food intake. Patients on metformin, an insulin-sensitizing agent, are unlikely to become hypoglycemic.

TABLE 37-5. An Example of the Separate Intravenous Glucose and Insulin Regimen

Plasma Glucose mg/dL	Insulin U/h	Insulin U/kg/h
<80	0.5	0.5
80–120	1.0	1.0
121–160*	2.0*	2.0
161–200	3.0	3.0
201–250	4.0	4.0
251–300	5.0	5.0
>300	6.0	6.0

*The regimen should be personalized to the patient, such that this dose is calculated as the patient's usual total daily insulin dose (all regular and intermediate- or long-acting insulin doses taken in one normal day) divided by 24. The doses for measured plasma glucose outside this range are then increased or reduced by 1 U/h for each range above or below this target. The insulin scale can be rewritten if needed to keep plasma glucose in the 121–160 mg/dL range.

Glucose: 10% dextrose containing 20 mmol KCl per liter, 100 mL/h

Insulin: 50 units regular insulin made up to 50 mL in 0.9% saline = 1 U/mL

but any fall in renal perfusion associated with the anesthesia or the surgery increases their risk of lactic acidosis. Sulfonylureas are insulin secretagogues and carry a high risk of hypoglycemia, especially the longer-acting agents such as glyburide, and with this agent hypoglycemia is likely to be both late in onset and prolonged. There are no data on surgery in patients on thiazolidinediones or meglitinides. In all cases the drugs should not be taken on the day of surgery. Long-acting sulfonylureas should perhaps be withdrawn sooner. Our previous recommendation that metformin be stopped two or three days preoperatively are not justified by its pharmacokinetics, and this too can just be withheld on the operative day.³⁶

The main determinants of therapy in the T2DM patient are: (1) the seriousness of the surgical procedure; and (2) the metabolic state of the patient on the day of surgery. The exception is the insulin-treated T2DM patient, who should be treated as a T1DM patient.

There is general agreement that the patient who is well controlled on diet alone or diet plus sulfonylureas does not require any specific therapy for minor surgery. Indeed it has been shown that new metabolic abnormalities may be produced by use of insulin infusions in this group,³⁷ although blood glucose values did reach a mean of 200 mg/dL (10 mmol/L) postoperatively in the untreated patients. In other studies we have shown pre- and postoperative glucose values of 140–155 mg/dL in such patients, well within the desirable target range.

There is more controversy as to how the poorly-controlled T2DM patient should be treated for minor surgery. Some still advocate no specific therapy, but this seems unwarranted and a glucose/insulin infusion regimen would seem appropriate. A fasting plasma glucose of 200 mg/dL (11.1 mmol/L) is an appropriate cut-off, because metabolic deterioration seems to occur with minor surgery only at higher levels.

Many different regimens have been suggested for metabolic control during major surgery in T2DM patients. One group has even suggested no insulin and no glucose.²⁸ It is logical and simpler, however, to use the same regimen as for T1DM patients. This does give similar results in terms of glycemic regulation.

Practical Guidelines: Minor Surgery

Preoperatively, control should be improved and long-acting sulfonylureas should be stopped as discussed above. On the day of surgery, drug therapy is withheld and fasting blood glucose checked with a test strip and meter. If blood glucose is <200 mg/dL, surgery is carried out as planned. If blood glucose is >200 mg/dL, a standard GIK or IP/GK protocol is commenced and the patient treated as a T1DM patient. It should be noted that many T2DM patients are obese and may need 40 U insulin/L 10% glucose in a GIK regimen rather than the standard 30 U.

Practical Guidelines: Major Surgery

Preoperatively, control should be optimized and short-acting insulin therapy used for the 24–48 hours before operation, if possible, in patients with unsatisfactory glycemic control. On the morning of surgery sulfonylurea therapy is withheld, an infusion regimen is commenced, and the fasting blood glucose level is checked. Thereafter management is as for the T1DM patient.

Postoperative Management

In all patients who have received GIK, blood glucose should be checked every 1–2 hours following surgery until stable glycemia is achieved, and then every 4 hours. Potassium should be checked

6 hours postoperatively and again on the following day, although it is rare to have to change the potassium content of the infusate. The GIK or separate insulin/glucose infusions are continued until the patient begins to eat again. At that time the usual preoperative SC insulin dose is given. The GIK mixture should be continued for another hour or so to allow absorption of some of the SC dose. If resumption of feeding is delayed, then parenteral nutrition can be instituted with insulin still given by the IV route. In this situation it should be given via a separate line using an infusion pump.

In T1DM patients who have not received GIK, their usual therapy is recommended with the first meal. Blood glucose should be monitored immediately postoperatively and pre- and 2-hour post-meal glucose monitoring done until stable values are obtained.

Good glycemic control postoperatively is paramount. It has been clearly shown that wound infections are fewer in better-controlled patients, although a precise threshold has not been established.^{38,39}

SPECIAL SITUATIONS

Day Surgery

In recent years there has been a dramatic increase in day or outpatient surgery. Nowadays nearly half of all surgical procedures are performed on a day surgery or outpatient basis, and the proportion is rising worldwide. It is certainly not necessary for all diabetic patients to be excluded from this group.

In T2DM patients, day surgery is appropriate for all minor procedures. However, preoperative assessment a few days before surgery is a *sine qua non*.⁴⁰ Patients should be treated as outlined above and scheduled for operation early in the day. Cataract surgery under local anesthesia in T2DM patients is entirely safe as an outpatient or day procedure.⁴¹

Insulin-treated patients may present a greater problem, but with appropriate preoperative assessment, the availability of blood glucose monitoring equipment, and good patient education; they can also be treated as day patients. Particular care will be needed for patients using long-acting analogs, the dose and which may need adjusting. The patients should also be scheduled for early operation and should be given IV insulin as discussed above. Subcutaneous insulin is recommended as soon as possible postoperatively and appropriate carbohydrate given. This applies of course to minor surgery. Blood glucose levels should be checked at the bedside hourly.

Emergency Surgery

Emergency surgery is at least as likely in the diabetic as the non-diabetic subject. Management will depend to a large extent on the metabolic condition of the patient. Surgical emergencies, particularly if there is underlying infection, can cause rapid metabolic decompensation with dehydration, hyperglycemia, and ketoacidosis. Uncontrolled diabetes may also be precipitated in patients not previously known to have diabetes. One trap for the unsuspecting is that patients with diabetic ketoacidosis (DKA) can present with symptoms indistinguishable from those of an acute abdomen. In these patients, the signs and symptoms resolve on metabolic correction. A useful rule of thumb is that if such patients are less than 20 years old, the problem is more likely to be metabolic, whereas if they are older, a genuine surgical emergency should be suspected. The sensible approach in such patients is to manage conservatively in the early stages with the emphasis on correction of the metabolic

derangement. If the problem is metabolic rather than surgical, then it will resolve in the next 3–4 hours.

Practical Guidelines

In all cases blood should be sent for immediate analysis of glucose, urea, and electrolytes as well as arterial pH and gases if clinically warranted. Plasma, urine, or both should be checked for ketones. It should be remembered that in the DKA patient, a raised white cell count does not necessarily indicate infection, but correlates with stress and blood ketone body levels.

If the patient is in early or established DKA, the first priority is metabolic management. Surgery should be delayed by 3–4 hours if at all possible. This will allow resolution of the pseudoacute abdomen as well as putting the patient in a better state to withstand the stress of surgery. Treatment comprises rapid saline infusion and insulin delivery via an infusion pump at 6 U/h. Potassium should be given in the saline (20 mmol/h), assuming adequate renal function. Glucose should be monitored hourly and electrolytes checked after 2–4 hours. Once blood glucose concentration has fallen below 270 mg/dL (15 mmol/L), a standard GIK or insulin pump regimen can be commenced, but with 40 U insulin/L 10% glucose for GIK or its equivalent because patients will be insulin-resistant. Blood glucose should be monitored hourly and the insulin content of the infusion increased if necessary.

In patients without severe metabolic disturbance, initial diabetic management is with a GIK or IP/GK protocol. Again, a higher-than-usual insulin concentration is likely to be needed.

Cardiopulmonary Bypass Surgery

Diabetic patients have a high prevalence of coronary artery disease and are therefore likely to undergo coronary artery bypass grafting. Morbidity and mortality are higher in the diabetic than the nondiabetic patient⁴² and it is possible that the intraoperative management of the diabetes contributes to this. Cardiopulmonary bypass (CPB) surgery involves the use of large volumes of exogenous fluid, hypothermia, and adrenergic agents, all of which can affect metabolic homeostasis. In the past, pump-priming fluids have often contained glucose and lactate. These should be avoided in the diabetic patient and replaced with plasma-like primers.

CPB is known to be associated with severe insulin resistance. When GIK is used for glycemic control, insulin:glucose ratios of 1–1.6 are needed, in contrast to the 0.3–0.4 used for routine elective surgery. Good results may be achieved by infusing insulin alone, with monitoring of blood glucose every 15–30 minutes by the anesthesiologist in the operating suite. Insulin requirements vary between 5 and 12 U/h. GIK is then introduced postoperatively. Clear indication of the benefits of using GIK therapy in diabetic patients undergoing coronary artery surgery has been reported.⁴³

It has also been suggested that hyperglycemia is associated with poor outcomes in diabetic patients undergoing cardiovascular surgery,^{26,44} particularly in the elderly.⁴⁵ This may well reflect effects on the CNS as well as impaired resistance to infection and impaired wound healing.

MORBIDITY AND MORTALITY

Factors influencing outcome in the diabetic include cardiovascular disease, liability to infection and poor wound healing. The latter can be counteracted by good glycemic regulation. However, car-

diovascular disease is a major cause of death in the peri- and post-operative periods.

Conflicting data have been published on whether diabetic patients have poorer outcomes following surgery. In general, poor outcome was related to poor glycemic control. Nowadays with good management of the diabetes, morbidity and mortality should be little increased in the diabetic population except in those with severe cardiovascular disease.

SUMMARY AND CONCLUSIONS

Surgery in the diabetic patient poses special problems—not only the metabolic problems of diabetes, but the susceptibility of the patient to cardiovascular disease, neuropathy, and infection also put the patient at special risk. Surgical stress is accompanied by increased secretion of the counterregulatory hormones and cytokines with resultant insulin resistance, inhibition of insulin secretion, and hyperglycemia. In T1DM patients without the ability to secrete more insulin, this will lead to metabolic deterioration. In T2DM patients with sluggish insulin secretion, there is already insulin resistance, and metabolic deterioration will also occur. The extent of the stress response to surgery depends, however, on the severity of the operation. Minor surgery leads to only minor metabolic derangement.

Therefore, in the well-controlled T2DM patient it is sufficient to withhold regular therapy on the day of surgery. In the poorly-controlled T2DM patient and in all T1DM subjects, insulin therapy is required. Many regimens have been proposed. The simplest is the combined glucose-insulin-potassium (GIK) infusion, which can be used from the morning of surgery until the patient is eating again. In better-staffed and -equipped centers, insulin can be given by separate infusion pump. Meticulous monitoring of plasma glucose is essential and appropriate sliding scales used to regulate dosage.

Certain special situations are also found. With proper attention to preoperative assessment, day surgery is safe for diabetic patients for minor operations. Emergency surgery is more common in the diabetic subject. The *sine qua non* is to correct any severe metabolic disturbance before embarking on surgery. The GIK or insulin pump regimen is then used. Cardiopulmonary bypass surgery is also a particular problem in diabetes patients because of massive insulin resistance. Here insulin is given intraoperatively without accompanying glucose, standard IV insulin being reinstituted post-operatively.

With appropriate care, the outcome of surgery in the diabetic patient should be little worse than in the nondiabetic patient when matched for clinical status, particularly cardiovascular disease.

The Mother in Pregnancies Complicated by Diabetes Mellitus

Boyd E. Metzger

Richard L. Phelps

Sharon L. Dooley

In 1882, in one of the first published reports of diabetes in pregnancy,¹ J. Mathews Duncan qualified his clinical observations with the following prescient caveat:

The advance of physiology makes it certain that pregnancy brings about important changes in the quantity or constitution of the blood, the bones, the skin, and its appendages, the heart, and the great glands, and makes it highly probable that every solid and fluid constituent of the frame is profoundly modified for the time.

He therefore suggested that the effects of pregnancy upon any disease should only be evaluated in the context of the changes that occur in the course of normal pregnancy. Insofar as normal pregnancy profoundly affects every aspect of intermediary metabolism,^{2,3} the comments of J. Mathews Duncan remain particularly germane to the relationships between diabetes and pregnancy.

METABOLIC ADAPTATIONS IN NORMAL PREGNANCY

Clinical Features of Carbohydrate Metabolism in Pregnancy

Alterations in carbohydrate metabolism are especially prominent in the second half of pregnancy.² Historically, it was observed that the disposition of administered glucose is only minimally altered in the normal gravida, whereas the hypoglycemic response to insulin is markedly attenuated.^{4,5} This dichotomy has long suggested that an enhanced resistance to insulin action exists as part of normal pregnancy, so that an increased elaboration of insulin is required to maintain normal glucose tolerance.⁶ Pregnancy is, therefore, a truly physiologic challenge to insulinogenic reserve. The histologic finding of islet cell hyperplasia during normal gestation and clinical experience in subjects with diminished or absent pancreatic β -cell reserve are in accord with this premise. Thus, pregnancy may be attended by onset or first recognition of carbohydrate intolerance (i.e., gestational diabetes mellitus [GDM]⁷⁻⁹), and substantial increases in the requirements for insulin may supervene in women with known insulin-requiring diabetes (i.e., pregestational diabetes mellitus). The

changes parallel the growth of the conceptus: they become increasingly manifest as the conceptus rapidly increases in mass from weeks 20–24 of pregnancy onward, and they are promptly reversed following expulsion of the conceptus.¹⁰ Accordingly, in the immediate postpartum period, normal glucose tolerance returns in most women with GDM, and insulin requirements decline precipitously to nongravid levels in patients with insulin-requiring pregestational diabetes. These temporal correlations have implicated the conceptus in the diabetogenic challenges that are part of normal pregnancy.¹⁰

Metabolic Contributions of the Conceptus

The conceptus (fetus and placenta) arises *de novo*; several of its functional properties exert metabolic effects during its development.¹¹ Maternal insulin does not cross the placenta, although some may be sequestered and bound there.¹² Insulin can also be degraded in the rat and human placenta, and the degradation coincides with accelerated removal of insulin from the maternal circulation in polytocous species, such as the gravid rat.^{13,14} In monotocous species such as humans, blood flow to the placenta represents a relatively smaller proportion of cardiac output than it does in rodents.¹⁵ Nevertheless, Catalano and colleagues^{16,17} have recently confirmed a moderate increase in insulin clearance in normal pregnancy and in GDM.

In contrast to the modest effects of human pregnancy on insulin turnover, dramatic changes occur in insulin secretion and insulin action.¹⁰ In early pregnancy, basal insulin concentrations are unchanged, and insulin responses to oral or intravenous glucose are only minimally increased.^{16,18-20} On the other hand, basal and stimulated values for plasma-immunoreactive insulin are greatly increased in late human pregnancy.^{18,20-22} It has been documented that the increase in circulating levels of immunoreactive material truly represents insulin rather than immunoreactive components with lesser biological potency.^{23,24} In normal lean subjects, insulin sensitivity begins to decrease by the end of the first trimester of pregnancy¹⁸ and is greatly reduced in late gestation.^{17,18,22,25}

Some quantitative estimations have been made. Pooled data from a number of laboratories indicate that the total output of insulin in response to oral glucose increases two- to threefold throughout pregnancy.¹⁰ More detailed recent analyses of intravenous glucose

tolerance have shown that during the third trimester the first and second phases of glucose-stimulated insulin release are increased about threefold in normal gravida. This "extra" insulin compensates for a reduction of approximately 40–60% in the responsiveness of the periphery to insulin action.^{17,18,22} The temporal patterns of insulin sensitivity before conception and during early and late gestation in normal pregnancy and gestational diabetes mellitus are shown in Fig. 38-1. When the integrated values for insulin secretion in response to glycemic challenge at various points in gestation are expressed as percentages of the values observed with similar challenges in nonpregnant subjects, the curvilinear pattern of progressive increases simulates the growth pattern of the conceptus (Fig. 38-2).¹⁰

Two properties of the developing conceptus have been implicated in the diminished sensitivity (i.e., the increased resistance) to insulin in late pregnancy: the endocrine function of the conceptus and the effects of the conceptus on maternal fuels. The precise mechanisms through which either of these properties of the conceptus could alter insulin sensitivity have not been fully elucidated.²⁶ Insulin resistance appears to be present in liver, adipose tissue, and skeletal muscle. The binding of insulin to receptors on circulating monocytes or erythrocytes, hepatocytes, and skeletal muscle is not diminished in human pregnancy, and it is clear that the insulin resistance of late human pregnancy is mediated by events distal to the binding of ligand to receptor.^{27–32}

However, efforts to pinpoint specific pathways that are responsible have yielded variable results. Content of GLUT4 transporters have been reported to be unaffected by pregnancy in muscle tissue of humans³³ and rats.³⁴ By contrast, GLUT4 transporters have reported to be reduced in adipose tissue of pregnant rats³⁴ and humans with normal pregnancy or GDM.³⁵ Insulin-stimulated tyrosine kinase activity of hepatic insulin receptors was reported to be decreased in rats during late pregnancy.³¹ In another study,³² autophosphorylation of skeletal muscle insulin receptors was reported to be unaffected by normal pregnancy or GDM. Recently, Shao and coworkers³⁶ investigated skeletal muscle insulin receptor tyrosine kinase activity in obese women with GDM or normal pregnancy. They found no changes under basal conditions, but insulin-stimulated insulin receptor function was impaired. They at-

FIGURE 38-1. Longitudinal changes in insulin sensitivity in women with normal pregnancy or gestational diabetes mellitus. Data from before pregnancy (pre-gravid) and early and late pregnancy are expressed as insulin sensitivity index (mean $\pm$ SD). **Solid bars**, controls; **hatched bars**, women who developed GDM. (Adapted with permission from Catalano et al.⁶⁷)

FIGURE 38-2. Effect of pregnancy on stimulated insulin secretion. The increases in plasma insulin above basal values following stimulation with glucose were summated to assess net secretory response. Published values from normal pregnant and nonpregnant women have been employed to derive the comparisons depicted previously. (Reproduced with permission from Freinkel.¹⁰)

tributed this to tyrosine kinase inhibition by increased levels of a cell membrane glycoprotein-1 (PC-1), which resulted in increased rates of serine/threonine phosphorylation and reduced levels of tyrosine phosphorylation.

The Conceptus as an Endocrine Structure

Increased secretion of progesterone, human placental lactogen (HPL; human chorionic somatomammotropin [HCS]), and estrogen by the placenta during pregnancy tends to parallel the growth of the conceptus.¹⁰ Each hormone has been shown to augment islet secretory responsiveness and to alter the sensitivity to insulin action in the periphery, although the status for estrogen remains somewhat controversial.³⁷ For example, HCS can exert lipolytic effects *in vitro*,³⁸ may induce insulin resistance in nongravid subjects when infused overnight in amounts designed to simulate the plasma levels that prevail during late gestation,³⁹ and has direct effects on islet structure and function.⁴⁰ Similarly, administration of progesterone to nongravid subjects can increase stimulated as well as basal insulin secretion⁴¹ and can augment such metabolic processes as gluconeogenesis. Estrogen can augment hepatic generation of circulating lipoprotein.⁴²

Thus, these hormones, which appear in ever-increasing amounts coincident with increasing placental mass, can create a metabolic setting distal to receptor binding in which the efficacy of a given amount of insulin is blunted and islet secretory performance is augmented. Moreover, their elaboration by the placenta is affected only minimally,⁴³ if at all, by the normal alimentary excursions of circulating nutrients. Consequently, although the acute hyperinsulinemia can offset their contra-insulin potentialities in the fed state, they are relatively unopposed in the fasted state. The finding that intrinsic rates of lipolysis and re-esterification are increased in adipose tissue isolated from rats⁴⁴ or humans⁴⁵ in late

gestation, even when sampling is performed in the fed state,⁴⁵ is consistent with this proposition.

Prolactin of pituitary and decidual origin⁴⁶ and the human growth hormone variant (hGH-V) of placental origin⁴⁷⁻⁴⁹ may also play some role in promoting resistance to insulin action.^{30,50} However, the precise metabolic contributions of these peptides during pregnancy remain to be defined. Some endocrine influences, not directly of intrauterine origin, may also contribute meaningfully. Glucocorticoids appear to be particularly important in this regard.³⁰ In human pregnancy, the exposure of maternal tissues to glucocorticoids is increased twofold above nongravid values,⁵¹ and an absolute increase of circulating free cortisol in the mother is well documented.⁵² It seems unlikely that these glucocorticoids are of fetal origin, or that autonomously functioning placental corticotrophin or corticotrophin-releasing factor activity⁵³ are responsible, since normal diurnal rhythms of cortisol secretion are preserved.⁵² Instead, maternal hypothalamic-pituitary feedback appears to be operative at a higher setting, perhaps as a result of the increased availability of sex steroids. Currently, potential roles of tissue necrosis factor- α ⁵⁴ and the recently discovered hormone of adipose tissue origin, leptin, are being investigated intensively.⁵⁵

Effects of the Conceptus on Maternal Fuels

Some abstraction of maternal fuels by the growing conceptus occurs continuously. Many of the nutrients are cleared from the maternal circulation in a concentration-dependent fashion² and are deployed for structural growth and development as well as oxidative needs. The fluxes are considerable: glucose utilization by the human fetus at term has been estimated to be 6 mg/kg/min⁵⁶ (in contrast to a rate of 2-3 mg/kg/min in normal adults⁵⁷). Growth of the human fetus during the third trimester requires the net transplacental transfer of 54 millimoles of nitrogen per day.⁵⁸ Consequently, maternal mechanisms for conserving 3-6-carbon nutrients may be compromised meaningfully as the pregnancy progresses and the fuel needs of placenta and fetus escalate.¹¹

Dietary deprivation during the latter half of pregnancy elicits more rapid and profound mobilization of fat^{44,59} and exaggerated increases in plasma and urinary ketones.⁵⁹ A greater and more rapid fall in maternal blood sugar⁵⁹⁻⁶¹ and amino acids⁶¹⁻⁶⁴ is also seen coincident with greater activation of intrahepatic gluconeogenesis^{59,65,66} and renal ammoniogenesis.^{59,61} The reduction in blood sugar may progress to frank hypoglycemia. It has been demonstrated that glucose turnover after overnight fast is increased in late human pregnancy,⁶⁷ as previously demonstrated in rodents.⁶⁸ This fasting hypoglycemia of pregnancy has been viewed as a *substrate deficiency syndrome*⁶² and ascribed to a failure of amino acid mobilization to "keep up" with rates of glucose removal.^{62,63} The integrated modifications of the fasted state in late pregnancy have been designated *accelerated starvation*.^{10,11}

Such features of "accelerated starvation" as enhanced ketonemia, increased urinary nitrogen, and exaggerated decrements in fasting plasma glucose (FPG) and circulating gluconeogenic amino acids are already manifest during midpregnancy.^{61,63,64} Some of the phenomena can be replicated by administering the hormones of pregnancy to nongravid subjects.⁶⁹⁻⁷² However, in pregnant rats, the difference in the metabolic response to fetectomy vs. hysterectomy suggests that full expression requires the presence of an intact conceptus.⁶⁹ Thus, at least part of the "accelerated starvation" must be ascribed to the continued abstraction of essential maternal nutrients by the growing placenta and fetus.

There has been some question as to whether "accelerated starvation" occurs under conditions that obtain in standard clinical

practice. However, it has been shown that the increases in plasma free fatty acids (FFAs), glycerol, and ketones and the reductions in plasma glucose and amino acids that are seen just before lunch when breakfast has been withheld are significantly greater in gravid than in nongravid women.^{73,74} Thus, the common clinical practice of "skipping breakfast" for laboratory tests or other clinical procedures may not be without meaningful metabolic consequences in late normal pregnancy.

Significant metabolic alterations are also seen in the fed state. The ingestion of glucose after overnight fast in late normal pregnancy elicits a greater and more prolonged increase in blood sugar, a greater increment in plasma very low-density lipoproteins,^{10,75} and a greater concurrent fall in plasma glucagon^{10,69,75-79} (Fig. 38-3). These changes in circulating glucose concentration are a manifestation of the insulin resistance of late gestation and are attended and perhaps facilitated by a delayed and reduced fall in FFA concentrations.^{75,76} This characteristic metabolic response has been designated *facilitated anabolism*.^{10,75,76} Since glucose crosses the placenta in concentration-dependent fashion,⁸⁰ the exaggerated hyperglycemia after glucose ingestion in late pregnancy results in greater availability of the dietary glucose for transplacental transfer. The increased plasma triglycerides can abet this objective by substituting for some of the circulating glucose as oxidative fuel in the

FIGURE 38-3 Effect of pregnancy on the response to oral glucose after overnight fast. Changes in plasma glucose, triglycerides, immunoreactive insulin, and glucagon are expressed as net increments or decrements from basal values after administration of 100 g oral glucose following a 14-hour overnight fast. The same normal women were used for paired "pregnant" vis-à-vis "postpartum" comparisons. (Reproduced with permission from Freinkel.¹⁰)

mother and thereby “sparing” glucose for transplacental flux. Moreover, since little if any triglyceride crosses the placenta,⁸¹ the carbohydrate-induced hypertriglyceridemia may also enable some of the ingested glucose to be retained for subsequent recall as triglyceride-glycerol or fatty acid during lipolysis in the fasted state.

Finally, the greater suppression of glucagon⁷⁷⁻⁷⁹ immediately after glucose ingestion may also “facilitate anabolism” in the fed state: it would blunt the contributions of glucagon to ongoing gluconeogenesis and ketogenesis and so spare ingested amino acids for maternal or fetal access. After disposition of the carbohydrate component of “mixed meals,” the well-preserved response of the α cells to amino acid stimulation of glucagon secretion^{82,83} could help to re-establish gluconeogenesis and so prevent exaggerated postprandial hypoglycemia and the full return to accelerated starvation.

PATHOPHYSIOLOGY OF DIABETES AND PREGNANCY

Morbidities associated with diabetes mellitus may affect both the pregnant woman and her offspring. This is illustrated by data from the preinsulin era, when maternal mortality approached 25%.⁸⁴ For several years after insulin treatment became widely available, perinatal mortality remained very high.⁸⁴ At the present time, maternal deaths have been largely eliminated. Under optimal circumstances, intrauterine fetal deaths are uncommon, and the incidence of neonatal deaths, except for those due to major congenital malformations, approaches that of the general obstetric population. However, other less extreme morbid outcomes continue to be common.

Effects of Diabetes on Pregnancy

Because newborns of pregnancies in which just the father has diabetes appear to develop normally,^{85,86} it is believed that morbidities in the offspring are due to abnormalities in the maternal metabolic environment, rather than genetic influences.

The late Jorgen Pedersen was the first to propose a mechanism whereby maternal fuels may exert a direct effect on the fetus. In attempting to explain the “large babies” that were often seen in pregnancies complicated by diabetes, he advanced the *hyperglycemia-hyperinsulinism hypothesis*.⁸⁷ He postulated that more maternal glucose gains access to the fetus whenever maternal insulin is inadequate and that this “extra” glucose stimulates insulin release in the fetus and thereby produces an increase of fetal mass. Subsequent work demonstrated that all maternal fuels may be awry in even the mildest forms of gestational diabetes and may increase the nutrients available for fetal growth, β -cell hyperplasia, and the premature activation of insulin secretion that Pedersen postulated. Accordingly, we later proposed that the Pedersen hypothesis be modified to include those maternal fuels besides glucose that are also regulated by maternal insulin (see Chap. 39, Fig. 39-1), and we likened pregnancy to a “tissue culture experience” since most of these fuels cross the placenta in concentration-dependent fashion.⁸⁸ Thus, their concentrations in the maternal circulation may determine the quantitative as well as qualitative characteristics of the “incubation medium” in which the conceptus develops.

In his 1980 Banting Lecture,¹⁰ the late Norbert Freinkel formulated the concept of *fuel-mediated teratogenesis* to draw attention to the relationships between maternal metabolism and fetal development throughout gestation. According to this hypothesis, the adverse effects of a metabolic disturbance would be conditioned by

the time in gestation when the event occurred and which cells were undergoing a critical stage of terminal differentiation at the time (Fig. 38-4). Thus, metabolic perturbations during organogenesis might be implicated in congenital malformations; those occurring in the second trimester might initiate pancreatic β -cell hyperplasia or have an impact on CNS development; a surfeit of metabolic fuels in late gestation might augment adipose tissue proliferation, fat synthesis, fetal obesity, and macrosomia. In the intervening two decades, much evidence has been collected in support of this hypothesis.

Congenital Malformations and Early Fetal Loss

Experimental, clinical, and epidemiologic studies indicate that the increased risks of congenital malformations and spontaneous abortions in pregnancies complicated by diabetes are linked to disturbances in maternal metabolism around the time of conception.^{10,89-91} The frequency of spontaneous abortions increases in direct proportion to glycohemoglobin concentrations measured in early pregnancy.^{92,93} The relationship between metabolic control and the risk of congenital malformations is more difficult to define (Fig. 38-5). The NIH-supported Diabetes in Early Pregnancy (DIEP) study found a 4.9% incidence of birth defects in patients recruited within 21 days of conception, a rate approximately twofold that in the nondiabetic control group (2.1%; $p = 0.027$).⁹² Most of the early entry DIEP study subjects were in *fair to good* glycemic control (glycohemoglobin within 7 standard deviations of the mean for controls in 93% of cases) during the first trimester. Green and colleagues⁹³ reported a prevalence of congenital anomalies of about 5% (almost identical to that of the DIEP Study) until first trimester glycohemoglobin concentrations exceeded the mean control value by 10–12 standard deviations (*poor metabolic control*), beyond which the rate of malformations increased greatly.

Exposure of rodent embryos in culture to marked hyperglycemia or rodent fetuses *in vivo* to severe maternal diabetes is associated with severe alterations of metabolic pathways including disruptions of signaling pathways, oxidative stress, and increased generation of free radicals.^{89,90,94-104} Any one or all of these disturbances may contribute importantly to diabetic embryopathy. However, even though the precise time or the duration of exposure to an

FIGURE 38-4. The hypothesis of “fuel-mediated teratogenesis.” It has been postulated that phenotypic gene expression in the newly forming cells of the conceptus may be modified by ambient fuels and fuel-related products during intrauterine development. Potential long-range effects will depend on the period in gestation during which maternal fuels and fuel-related products are aberrant and the cells that are undergoing development at that time. (Adapted with permission from Freinkel.¹⁰)

THERAPEUTIC DILEMMA IN EARLY DIABETIC PREGNANCY

FIGURE 38-5. Therapeutic dilemma in treatment with insulin during early human pregnancy. Hypoglycemia during the period of glycolytic dependence in the rodent embryo has been shown to be teratogenic. Whether the human embryo is similarly vulnerable during the corresponding developmental interval (i.e., about days 16–18 to days 24–25 post conception) has not been established. Moreover, the thresholds for the various factors in maternal serum that account for teratogenesis of diabetes (broadly designated above as “hyperglycemia”) have not been ascertained. Thus, the optimal target for metabolic regulation before and during the first 4–6 weeks after conception has not yet been precisely established. (*Adapted with permission from Freinkel.*⁹⁶).

abnormal metabolic environment necessary for adverse events to develop in the human embryo has not been pinpointed, substantial insight has been gained regarding their prevention. Several groups have reported encouraging results from efforts to provide counseling and improved control of diabetes mellitus prior to conception. In such circumstances, rates of major congenital malformations do not appear to be greater than expected in general obstetric populations; however, the studies have not included data on rates of malformation in concurrently examined controls.^{105–108} In Denmark, where the majority of pregnancies in women with diabetes are now planned, a nationwide decline in congenital malformations from 7.4 to 2.7% has been reported.¹⁰⁹ These developing trends have stimulated efforts to educate both health care professionals and patients concerning the benefits of preconception care. Unfortunately, the level of compliance in the United States remains substantially below that of the Danish population mentioned above.¹¹⁰

Disturbances in Fetal Growth

Neonatal macrosomia (traditionally defined as birthweight in excess of 4000 g or above the 90th percentile for gestational age) is a frequent complication of pregestational as well as GDM. Increased adiposity is the primary component of the macrosomia. Early measurements of fat cell number, size, and lipid content indicated that infants of diabetic mothers may have almost twice as much body fat as infants of normal mothers.^{111,112} Skinfold measurements at birth (an index of subcutaneous fat) have been used to document this adiposity and may correlate with the antecedent metabolic regulation.^{113,114} Infants of diabetic mothers tend to have significantly increased adiposity at their shoulders,¹¹⁵ which heightens the likelihood of shoulder dystocia, birth trauma, and cesarean section delivery. Using carefully standardized methods for neonatal anthropometry, Catalano's group¹¹⁶ has recently demonstrated an increased body fat content in offspring of mothers with GDM, even when total body weight was not increased above that

of the controls. Other insulin-sensitive tissues such as liver and heart are also often enlarged in offspring of diabetic mothers.¹¹² Although skeletal growth may not be dependent on insulin action, a modest increase in fetal height (length) is commonly found. Head size, although normal, often appears small because of the concurrent truncal obesity.

In lieu of more direct estimates of body fat content, Farquhar¹¹⁷ first used a simple expression of the relative proportionality between weight and height, which has been termed the symmetry index [SI] for clinical evaluation of the disparate growth of “insulin-sensitive” tissues. SI is calculated from the relationship between relative weight, W_t (i.e., observed weight/50th percentile weight), and relative height, H_t (i.e., observed height/50th percentile height), at that time, i.e., $SI = W_t/H_t$. Thus, whereas in symmetrically grown infants the SI would be expected to approach unity, in macrosomic infants with excessive weight-for-length, the SI is often greater than 1.2.

SI values in offspring of diabetic mothers have correlated with increased levels of several fuels in the maternal circulation in the second as well as the third trimester¹¹⁸ and with increased insulin or C peptide in amniotic fluid and cord blood, consistent with premature activation of fetal islet function.^{119,120} Others have also demonstrated correlation between amniotic fluid insulin or C peptide and neonatal macrosomia and morbidity in diabetic pregnancies.^{121,122} Persson and colleagues,¹²³ like the Northwestern University workers,¹¹⁸ have found that the premature activation of fetal islets correlates with maternal levels of insulinogenic amino acid as well as glucose.

Most infants who are large for gestational age, based on birth weight as the sole criterion, are born to women with normal carbohydrate tolerance.¹²⁴ Thus, gross birthweight is not a specific index of the effects of maternal diabetes on excessive fetal growth in late pregnancy, rather, asymmetric growth (with hypertrophy of insulin-sensitive tissues relative to those tissues whose growth is

little influenced by fetal insulin) is the characteristic feature of diabetic fetopathy. This asymmetric growth can be ascertained *in utero* by serial ultrasound measurements of the fetal abdominal circumference, which includes tissues manifesting "insulin-sensitive" growth (e.g., subcutaneous fat, liver), and fetal head circumference or biparietal diameter, which includes tissues whose growth is relatively "insulin-insensitive" (e.g., bony calvarium, brain).¹¹⁹

Excessive increase in abdominal circumference in the presence of normal head growth connotes the fetal macrosomia of diabetes mellitus. Fetal humeral soft tissue thickness has been shown to be an even more accurate predictor of asymmetric fetal growth, as confirmed by examination of the neonate.¹²⁵ Buchanan and coworkers¹²⁶ have used relative increase in abdominal circumference to identify pregnancies in GDM that are at high risk for macrosomic infants and to target this subgroup for more intensive medical therapy with diet and/or insulin. Finally, heavy neonates born to women with diabetes mellitus may not always represent examples of diabetic macrosomia. Keller and colleagues¹²⁷ observed a subset of infants of diabetic women in whom birthweights exceeded 4000 g but who had biparietal diameter, length, and birthweight proportionally or symmetrically increased from standard norms, and in whom amniotic fluid insulin concentration was not elevated.

Increase in the rate of insulin secretion in the fetus exposed to the metabolic milieu diabetes mellitus may begin during the second trimester. Histologic and morphometric studies in fetuses of mothers with diabetes delivered at this time have shown islet hypertrophy and hyperplasia.¹²⁸ Reiher and colleagues¹²⁹ compared stimulated insulin secretion *in vitro* from pancreases of fetuses of varying gestational age from diabetic women in poor metabolic control and nondiabetic women. Fetal insulin secretion was increased as early as 16 weeks of gestation in poorly controlled diabetes. We have found a stronger association between fetal islet function (amniotic fluid insulin [32–38 weeks of gestation] or cord plasma C peptide at delivery) and metabolic control in the second trimester (HbA_{1c} concentration) than in the third trimester.¹¹⁸ However, visceromegaly and the excessive deposition of fat occur primarily during the third trimester.

Studies in which insulin pumps were implanted in monkey fetuses have shown that hyperinsulinemia *per se* can accelerate the growth of insulin-responsive tissues, even without attendant increases in metabolic fuels.¹³⁰ Thus, if increased secretion of insulin from fetal β -cells begins prematurely in midgestation, it is conceivable that hyperinsulinemia and augmented fetal anabolism could continue even in the absence of persistent elevations of maternal nutrients.¹¹⁸ Although it is clear that insulin has direct effects on fetal tissues, concurrent increases in the levels of the insulin-like growth factors (IGF-I and/or IGF-II) or other growth factors may also be contributory.¹³¹

In the past, intrauterine growth retardation (IUGR), the converse of macrosomia, was frequently observed in offspring of insulin-dependent diabetic mothers. This was commonly thought to reflect "utero-placental insufficiency" secondary to maternal vascular disease.¹³² Current reports indicate that, except for pregnancies complicated by hypertension and/or diabetic nephropathy, IUGR is rarely seen.^{133,134} Concurrently, the occurrence of macrosomia in pregestational diabetic pregnancies has markedly increased, reaching rates of 30–40% in some reports. Clinical observations¹³⁵ and studies in animal models and in rodent embryo cultures¹³⁶ suggest that disturbances in maternal metabolism in early pregnancy may retard growth irreparably, with or without associated birth defects. Better control of diabetes in early pregnancy

and discontinuation of routine delivery before term may account for the rarity of IUGR and the increased prevalence of macrosomia in the newborns of women with pregestational diabetes.

Effects of Pregnancy on Diabetes

Glycemic Control

In normal pregnancy, insulin resistance induced by placental hormone production and the siphoning of maternal fuels by the conceptus (see above) is overcome by major increases in maternal insulin production, such that blood glucose concentrations remain within relatively narrow limits and are close to those seen in non-gravid women. With insulin deficiency, substantial increases in blood glucose and other insulin-sensitive fuels will occur unless they are counterbalanced by increased doses of exogenous insulin.

Catalano and coworkers⁶⁷ performed measurements of insulin sensitivity by the euglycemic-hyperinsulinemic clamp technique serially before and during pregnancy. Subjects who maintained normal glucose tolerance throughout (controls) showed a small, but significant reduction in insulin sensitivity by late in the first trimester (Fig. 38-1). A group with previous GDM and glucose tolerance in the normal range was somewhat insulin-resistant before pregnancy and showed a small, but significant increase in insulin sensitivity when they were retested late in the first trimester. In women with type 1 diabetes mellitus (T1DM), a mild reduction in insulin dosage is often seen toward the end of the first trimester (approximately 10–14 weeks of gestation).¹³⁷ This may be associated with more frequent and severe hypoglycemia. This pattern is most likely to occur in women who have suboptimal metabolic control in early pregnancy. Thus, aggressive efforts to achieve satisfactory glycemic control as quickly as possible may contribute to this tendency. In other cases, morning sickness (nausea and emesis) may result in erratic and unpredictable caloric intake in the first trimester. This may lead to marked swings in glycemic control including episodes of both severe hypo- and hyperglycemia, a problem that is particularly troubling during this period of organogenesis in the fetus. Whatever the factors responsible, it is important for clinicians to be aware of the tendencies toward less stable metabolic control in early pregnancy.

During the second trimester, insulin needs steadily increase, with the major increment occurring between 20 and 30 weeks of gestation, often reaching doses that are two- to threefold greater than in early pregnancy. The last several weeks (32–38 weeks) are characterized by relative stability of glycemic control, often requiring only minor modifications of insulin doses from week to week. In the last 1–2 weeks before delivery, some patients note more frequent hypoglycemia, and insulin doses may need to be reduced, especially those acting overnight. Immediately post partum, normal or supranormal insulin sensitivity is restored. Dramatic reduction of insulin doses (75–90%) may be necessary for several days. After that, insulin requirements usually become similar to what was needed before pregnancy.

Microvascular Disease

Retinopathy

Instances of severe deterioration in diabetic retinopathy during pregnancy have been documented.^{138,139} Reports from Northwestern University¹³⁹ and elsewhere¹⁴⁰ indicate that severe deterioration of retinopathy during pregnancy rarely, if ever, occurs in subjects with minimal or absent retinopathy prior to conception. Vision-threatening change is primarily confined to patients with se-

vere background retinopathy or untreated proliferative retinopathy already present before pregnancy or discovered in early gestation. By contrast, serious alterations in retinal status rarely occur during gestation in women with proliferative retinopathy who have been treated with photocoagulation and deemed "inactive" prior to conception.^{138,141} We, and others, have reported an association between worsening retinopathy during pregnancy and the magnitude of hyperglycemia at enrollment.^{139,140} Worsening retinopathy was also related to the magnitude of improvement in diabetic control achieved in the first half of gestation.

This finding suggests that some of the untoward ophthalmologic changes hitherto ascribed to pregnancy may be linked to the *rapid* institution of tight diabetic control in subjects whose diabetes was previously poorly regulated.¹³⁹ This phenomenon was noted in nongravid subjects in the Diabetes Control and Complications Trial (DCCT)¹⁴² and elsewhere.¹⁴³ Hypertension has also been associated with progression of retinopathy during pregnancy.¹⁴⁴ Recently, analysis of the data from the DCCT¹⁴⁵ indicated that pregnancy does contribute to transient progression of retinopathy. As in previous reports, some subjects developed severe enough retinopathy to require photocoagulation therapy during pregnancy. The analysis of the DCCT experience also indicated that progression of retinopathy can continue after pregnancy or that retinopathy can first appear in the first 6–12 months post partum. However, no permanent adverse affect of pregnancy on retinal status was found.¹⁴⁵ In other words, the tendency for progression that has been observed during gestation is transient.

Although photocoagulation therapy can be used effectively during gestation, it seems prudent to assess retinal status carefully beforehand and to delay conception until stabilization of retinal pathology has been achieved. By this means, the risks of accelerated retinal damage in association with pregnancy may be minimized for most women.

Nephropathy

Normal physiologic adaptations of pregnancy include an increased glomerular filtration rate (GFR), increased renal plasma flow, and afferent arteriolar vasodilation. These changes result in glomerular hyperfiltration, which may be maladaptive in patients with pre-existing renal disease, and an increased systemic pressure transmitted to the glomerulus in the setting of hypertension. In addition, pregnancy is associated with an increase in urinary tract infections and pyelonephritis secondary to ureteral hypomotility with vesicoureteral reflux, physiologic hydronephrosis, and increased urinary nutrient content. This combination of factors may, in certain instances, predispose to accelerated deterioration of renal function in pregnancy. Observations of patients with mild pre-existing diabetic nephropathy (microalbuminuria, proteinuria, or mild renal insufficiency with a creatinine < 1.4 mg/dL [124 mmol/L]) suggest that pregnancy does not permanently accelerate their nephropathy, although there may be a transient worsening of proteinuria and creatinine clearance.^{146–148} However, studies of diabetic patients with moderate or severe renal insufficiency raise the concern that pregnancy may accelerate the decline in renal function in such persons,^{149,150} as has been seen when patients have moderate renal insufficiency of nondiabetic etiology. In addition, pregnancy in women with more severe degrees of nephropathy may be complicated by exacerbation of hypertension/pre-eclampsia, acceleration of retinopathy, and fetal/neonatal morbidity (prematurity, IUGR).^{146,148,150} Prophylactic measures to preserve renal function include maintaining good glycemic and

blood pressure control, obtaining frequent urine cultures with antibiotic therapy as needed, and careful monitoring of maternal renal function and fetal well-being.

Neuropathy

Little is known of the effect of pregnancy on diabetic neuropathy, a complication that exists in 7–50% of patients after 1–2 years of diabetes duration, respectively. However, the presence of autonomic neuropathy may have a potentially adverse effect on maternal morbidity¹⁵¹ and pregnancy outcome.¹⁵² Gastroparesis is of particular concern, as the irregular gastric emptying may result in inadequate nutrition, marked fluctuation in blood glucoses, and maternal aspiration. Genitourinary disturbances in patients who have diabetic nephropathy and bladder dysfunction may result in recurrent urinary tract infection and worsening renal function.

Macrovascular Disease

Patients with macrovascular disease have significant risks of maternal and fetal morbidity. First, pregnancy may exacerbate pre-existing vascular disease. Systolic blood pressure may increase significantly in T1DM women, whereas diastolic blood pressure tends to be higher than in controls at conception and throughout gestation.¹⁵³ In a limited number of cases reported, myocardial infarction in pregnancy has been associated with a 50% mortality rate.^{141,154,155} Since these reports were published more than 3 decades ago, the outcomes may not reflect risks with current practice. Women with coronary artery disease are also vulnerable to myocardial infarction and congestive heart failure in the immediate postpartum period.

CLASSIFICATION OF DIABETES IN PREGNANCY

Pre-existing insulin-treated diabetes is a complicating event in approximately 0.2–0.5% of all pregnancies in the United States.¹⁵⁶ In some populations, half or more of such pregnancies are in women with type 2 diabetes mellitus (T2DM) rather than T1DM (insulin-dependent). GDM affects an additional 2–6%. These figures are likely to increase in the future, because the incidence of obesity and T2DM seem to be increasing in adolescents and young adults, especially among minority populations. Since there are more than 3,000,000 live births in the United States each year, diabetes during pregnancy constitutes an appreciable and increasing public health problem.

In accord with recommendations of the National Diabetes Data Group,⁷ the 1997 Expert Committee on the Diagnosis and Classification of Diabetes Mellitus,⁹ and the Fourth International Workshop Conference on GDM,⁸ gestational diabetes is defined as "carbohydrate intolerance with onset or first recognition during the present pregnancy." We continue to subdivide GDM on the basis of the severity of the metabolic disturbance^{10,120,157,158} and use FPG as the distinguishing characteristic (Table 38-1). To be consistent with changes recently introduced to define an elevated FPG concentration during pregnancy, we designate gravida as GDM Class A₁ when values for FPG are within the normal range for pregnancy, (i.e., <95 mg/dL [5.3 mmol/L]) and as GDM Class A₂ when values equal or exceed this limit.

For epidemiologic purposes, pregnant women with abnormal glucose tolerance who had gestational diabetes with a prior pregnancy are not considered to have gestational diabetes with the current pregnancy. Unless post- or interpartum testing indicated a

TABLE 38-1. Classification of Carbohydrate Intolerance During Pregnancy*

Class	Classification Criteria
Gestational diabetes mellitus (GDM)	Carbohydrate intolerance of varying severity with onset or first recognition during the present pregnancy. Diagnosis as per Tables 38-2 and 38-3. Antepartum subclassification on the basis of values for fasting glucose.
<i>GDM Class A₁</i>	Fasting glucose normal for pregnancy: venous plasma < 95 mg/dL (5.3 mmol/L)
<i>GDM Class A₂</i>	Fasting glucose exceeds normal for pregnancy: venous plasma ≥ 95 mg/dL (5.3 mmol/L) on at least two occasions
	<i>Postpartum Reclassification</i>
	Evaluation by fasting plasma glucose or 75 g oral glucose tolerance test to classify according to the criteria of the NDGG and ADA Expert Committee as: "Previous abnormality of glucose tolerance (GDM)" if glucose tolerance normal at this time, or impaired fasting glucose, impaired glucose tolerance (IGT), or diabetes mellitus
Previous GDM	Abnormality of glucose tolerance in a previous pregnancy, without diabetes mellitus having been diagnosed postpartum (postpartum glucose tolerance test normal, impaired fasting glucose, IGT, or not performed) (See above for fasting plasma glucose parameters.)
<i>Previous GDM: Class A₁</i>	
<i>Previous GDM: Class A₂</i>	
Pregestational diabetes mellitus	Diabetes mellitus diagnosed prior to the present pregnancy (according to criteria of the ADA Expert Committee)
<i>Diabetes mellitus type 1</i>	
<i>Uncomplicated</i>	Absence of retinopathy, nephropathy, neuropathy, coronary artery disease, or hypertension
<i>Complicated</i>	Presence of one or more of the above (see footnote for designation and definitions)†
<i>Diabetes mellitus type 2</i>	
<i>Uncomplicated</i>	As for type 1 diabetes
<i>Complicated</i>	As for type 1 diabetes

* Classification is based on prevailing practices in the authors' center and the recommendations of the National Diabetes Data Group (NDDG), the ADA Expert Committee, and the Workshop Conferences on Gestational Diabetes.^{7,9}

† BDR, background diabetic retinopathy; PDR, proliferative diabetic retinopathy; NEPH, diabetic nephropathy defined as ≥0.5 g protein in 24-hr urine collection and/or serum creatinine consistently ≥1.2 mg/dL (106 mmol/L); NEUR, neuropathy, defined as known gastroparesis when not pregnant, orthostatic hypotension, or sensory abnormalities in lower extremities detected at bedside examination; CAD, coronary artery disease diagnosed by history, ECG, or stress ECG; HTN, hypertension, defined as BP ≥ 140/90 consistently. (Designations are appended to primary diagnosis as appropriate, e.g., diabetes mellitus-type 2-uncomplicated; diabetes mellitus-type 1-BDR, NEPH, etc.).

Source: From Metzger *et al.*,¹³⁷ with permission.

diagnosis of diabetes mellitus, they are classified as Previous GDM and subdivided on the basis of FPG concentration into Class A₁ or Class A₂ (Table 38-1). Patients who had normal or impaired glucose tolerance (IGT) or impaired fasting glucose post partum, as well as patients in whom the interpartum status is unknown, are included in the Previous GDM category.

We, as well as some others, have ceased to use the traditional classification devised several decades ago by White.¹⁵⁹ That scheme is based on the age of onset of diabetes mellitus, its duration, and whether or not micro- or macrovascular complications are present. At the time of its formulation, this was useful in predicting the risk of perinatal loss or serious morbidity. In the present era fetal losses are uncommon, and the degree of metabolic control throughout pregnancy and the presence or absence of vascular complications, independent of maternal age or duration of diabetes mellitus, are more specific predictors of maternal or fetal morbidities. We attempt to distinguish those pregnant patients with T1DM from those with T2DM.⁹ Although this distinction cannot be made with certainty in every case, the standard clinical yardsticks are generally reliable. Groups are then subdivided based on whether diabetic complications are known to be present. Abbreviations for the specific complications are added as postscripts (Table 38-1).

MANAGEMENT

Pregestational Diabetes

Preconception Counseling

Under optimal conditions, the management of "pregnancy complicated by diabetes" should begin before pregnancy is even contemplated. Information about the potential complications of pregnancy for mother and offspring should be an essential aspect

of the education of all women with diabetes mellitus. The educational efforts should be initiated as early as possible, ideally by the time of puberty. The precise content and mode of presentation are necessarily tailored to the age and level of maturity of the individual patient. However, it should be repeatedly emphasized that pregnancy may introduce uniquely new problems, if special precautions are not taken in advance. Thus, contraception should be discussed and offered to all women of childbearing age who have diabetes mellitus. Ideally, the woman's satisfaction with her contraceptive practices should be assessed at every contact whether or not that visit is intended as a preconception consultation. An ongoing dialogue with the woman allows reinforcement of the concept that a planned conception after appropriate assessment and improvement of metabolic control will reduce the risk of pregnancy complications such as spontaneous abortion and fetal malformations.

For women seeking preconception advice (ideally offered with the prospective father in attendance), reassessment of maternal health status is undertaken, with particular attention given to possible diabetic vascular complications. In addition to a complete physical examination, including pelvic examination, we recommend ophthalmologic consultation unless diabetes is of short duration and routine funduscopy examination appears to be normal. We also obtain baseline measurements of glycohemoglobin, thyroid-stimulating hormone (TSH), 24-hour creatinine clearance and quantitative urinary protein excretion (micro- or macroalbuminuria as appropriate), complete blood count (CBC), and an automated chemistry screen. Immunity to rubella should also be assessed, with immunization of susceptible individuals. Lifestyle issues should be reviewed for needed adjustments, including assessment of stress, tobacco or alcohol use, and prescription drugs that may need to be discontinued prior to pregnancy. In particular,

this often means the discontinuation of angiotensin-converting enzyme (ACE) inhibitors, agents that are increasingly being used early in the treatment of hypertension and microalbuminuria.

Information relating to the potential effects of diabetes on fetal growth and development (see above), including long-range outcomes (see Chap. 39), is reviewed with the prospective parents, emphasizing the benefit of careful diabetic control before and during gestation. The possibility of deleterious effects of pregnancy on maternal vascular complications (see above) is also discussed as the mother's clinical condition warrants. The patient and significant other(s) should also be reminded that prenatal care is intensive and involves a significant time commitment for the greater frequency of prenatal visits and the additional efforts that are needed to maintain optimal metabolic control in the period before conception and during the entire pregnancy. The possibility that fetal and neonatal effects of maternal diabetes (pregestational or gestational) may have a long-range impact on the offspring is an issue with major public health implications. Presently, many studies have focused on the possibilities that obesity, T2DM, and neurobehavioral deficits may be more prevalent in later life in the offspring of diabetic mothers (see Chap. 39).

To minimize the likelihood of birth defects and/or diabetes-related spontaneous abortions, we strive for good, stable metabolic control *before* conception.^{90,137} This requires a period of renewed effort for patients already familiar with an intensive management regimen and an introduction to the concept of *tight control* for others. Periconceptional supplementation with folic acid may reduce the risk of neural tube birth defects,¹⁶⁰ and neural tube defects occur at an increased rate when pregnancy is complicated by diabetes. We advise women to start a multivitamin containing 0.8 mg folic acid prior to the intended conception. This should be continued through the first 6 weeks of gestation.

Glucose regulation is assessed by capillary blood sugar measurements performed by the patient and by estimates of HbA_{1c}. We prescribe a diet based on a "exchange system" and set up a multiple-dose insulin injection algorithm for those women who are not currently using an intensive diabetes management program. An experienced caregiver reviews the results of capillary blood glucose tests with the patient at least weekly. Many women, particularly those who use pumps for delivery of insulin, have varying degrees of familiarity with the practice of "carbohydrate counting" wherein the premeal dose (bolus) of short-acting insulin that is given takes into account the grams of carbohydrate that are to be ingested. Many women use this effectively and also maintain a balanced intake of protein, fat, and micronutrients. We do encourage them to maintain more day-to-day consistency in meal time and meal size than they may have done outside of pregnancy. This is particularly helpful during the time of rapidly escalating insulin requirements. Others need more guidance to ensure intake of an adequate number of calories and optimal balance of nutrients. We expect to see corroboration of the improved control by stabilization of glycohemoglobin concentration within or near the normal range before contraception is discontinued. In many cases this entire effort may encompass an interval of 3–4 months.

Management After Conception

T1DM complicates pregnancy infrequently, and expertise in the management of this high-risk population can only be achieved if sufficient numbers of patients are seen on an ongoing basis. Optimally, therefore, such care is provided in specialized referral clinics, employing a team consisting of physician, nurse educator, nutrition-

ist, and social worker (depending on the population served) whose practices and philosophies are consistent and well integrated.

Diet

Diabetes does not alter the basic dietary recommendations for pregnancy, except that complex carbohydrates should be substituted for "free" sugars. Because of the heightened propensity for accelerated starvation,^{73,74} inclusion of an evening snack is recommended. Carbohydrate intake is seldom restricted below 200 g/day and food intake should be distributed throughout the day to avoid periods of fasting in excess of 4–5 hours during the waking hours. The proportion of the daily diet given at specific times can be individualized (within the above constraints) according to patient preference and may also be manipulated to effect stability of metabolic control. However, consistency from day to day is essential for the attainment of excellent diabetic control.

In the interest of simplicity (which we believe enhances adherence to the overall treatment regimen), we usually plan a diet of three major meals and a bedtime snack. Some caregivers recommend multiple small feedings (six to seven) throughout the day in an effort to dampen postmeal hyperglycemia. Whether the meal 24-hour blood glucose is lower with such regimens is unknown (Dampening postprandial peaks by frequent small meals might be associated with higher premeal glucose concentrations.) Proponents of a multiple-feeding regimen that focuses on control of postprandial hyperglycemia base this approach on the findings in some reports of a stronger correlation between mean values of postprandial glycemia and birthweight than between fasting and premeal glycemia and birthweight.^{161,162} However, these were observational findings, not prospectively designed studies. Furthermore, it is not certain what influence day-to-day variability in glycemic control, in contrast to the overall average level of glycemia, may have on perinatal outcome.

Dietary prescriptions are individualized and modified over the course of gestation. The Institute of Medicine of the National Academy of Sciences has published guidelines relating to optimal weight gain during gestation¹⁶³; in the absence of information to the contrary, we consider these recommendations to be appropriate for pregnancy complicated by diabetes. Accordingly, it is recommended that gestational weight gain be inversely proportional to the degree of adiposity in the mother before conception. This may vary from 15 pounds (7 kg), in the very obese, to 40 pounds (18 kg) for underweight women. Adiposity is judged by body mass index (BMI), defined as weight/height². A prepregnancy BMI of 19.8–26.0 kg/m² is considered normal, in which case a 25–35-pound (11–16 kg) weight gain is judged desirable. For those with BMI < 19.8 kg/m², the recommended weight gain is 28–40 pounds, and for those with BMI > 26 kg/m², it is 15–25 pounds. Additionally, some experts have estimated that the caloric cost of pregnancy may be only 100–150 kcal/day above requirements outside of pregnancy.¹⁶⁴ This is substantially less than the 250–300-kcal/day figure that was widely accepted in the past as the basis for dietary prescriptions. Thus, we find it very important to monitor weight gain closely during pregnancy and to modify caloric intake to reach the goals that are summarized above.

We base the initial prescription before conception or in early gestation on an estimate of the woman's weight-maintenance caloric intake, or we use an estimate based on 32 kcal/kg ideal body weight (IBW).¹⁶⁵ This is increased to 35–38 kcal/kg IBW after the first trimester, depending on appetite, physical activity, and weight gain. Dietary protein accounts for 1.5–2.0 g/kg IBW

carbohydrates comprise 50–55% of total calories, and fat comprises 30–35%. For women who become pregnant while using carbohydrate counting to guide their dietary intake, care must be taken to achieve an adequate intake of the full spectrum of nutritional needs for pregnancy (see above).

Variations of up to ± 25 –30% in total calories may be necessary to attain optimal weight gain as described above. In some centers, a relatively large proportion of women with pregestational diabetes have T2DM and are obese. The use of hypocaloric diets to restrict weight gain below the guidelines outlined above has been advocated by some¹³² (for review, see ref. 165). Moderate caloric restriction (20–25% below the figure cited above) may reduce hyperglycemia without increasing ketonemia or promoting the development of ketonuria. However, since “around the clock” studies in obese women with GDM whose caloric intake was restricted more than 33% below standard prescriptions have shown significant elevations of FFAs and plasma ketones,¹⁶⁶ we do not advocate this degree of caloric restriction, except in a research setting. High-fiber diets have not been found to be effective in reducing postprandial plasma glucose levels during pregnancy. “Isocaloric diets” containing only 30–40% of calories as carbohydrate (rather than 50–55%) do effect a reduction in hyperglycemia,¹⁶⁷ but the effects of the concomitant increase in dietary protein and fat on maternal amino acids, lipids, and ketones have not been investigated in detail.

Insulin

Optimal therapy necessitates individualization. We have used “intensified” therapy routinely since 1970. We ask our patients to supplement the longer acting insulin (given at breakfast, supper, or bedtime as necessary to maintain *basal* insulinization) with soluble insulin given prior to each meal (to replicate acute postprandial insulin excursions).¹⁰ Lispro insulin (Humalog[®]), an analog of human insulin, is more rapidly absorbed from subcutaneous tissue than is Regular (soluble) human insulin. Postinjection profiles of circulating Humalog have been shown to mimic the profiles of secreted insulin in normal subjects more closely than the pattern seen after injection of Regular human insulin.¹⁶⁸ Increasing numbers of women are using lispro insulin for their usual treatment and are thus on this therapy when they are seen for evaluation before pregnancy. In nonpregnant subjects, many studies have shown its superiority in controlling postprandial hyperglycemia; it has also resulted in some reduction in the frequency of hypoglycemia. Only limited information is available concerning its efficacy and safety in pregnancy. However, no untoward events have been conclusively ascribed to its use during pregnancy.¹⁶⁹ We do not discourage its use in women who are already using lispro insulin when they are seen for preconception care or when they enroll for prenatal care at our center after they conceive. In many patients, bolus injection of lispro insulin must be supplemented with low doses of intermediate-acting insulin or used in combination with Regular insulin to ensure that hyperglycemia does not ensue before the next meal as a result of complete disappearance of lispro insulin. Other analogs and modified forms of insulin are in development. When they are released for clinical use, there will be uncertainties regarding their use during pregnancy like the circumstances that occurred after the introduction of lispro insulin.

Whatever insulin preparations are used, doses are adjusted in an effort to achieve fasting and premeal blood glucose concentrations of 65–85 mg/dL (3.6–4.7 mmol/L) and 1- or 2-hour postprandial values of <140–150 and 120–130 mg/dL (7.7–8.3 and 6.7–7.2 mmol/L), respectively. Patients are provided with individu-

ally tailored algorithms for adjustments of insulin doses at each injection. These are altered as necessary by telephone or at clinic visits. This variable, multidose regimen provides for greater flexibility in responding to the erratic blood sugar fluctuations that often occur in patients with T1DM. The use of insulin pumps and continuous subcutaneous insulin infusion (CSII) with bolus infusions prior to meals has not been shown to confer any greater benefits in pregnancy than the program of intensified conventional therapy cited above. We continue CSII therapy for patients who have been using it prior to conception; however, we do not initiate its use during pregnancy unless patients are strongly motivated to do so.

Most patients with T2DM retain some endogenous insulin secretion. In such patients, it is often relatively easy to achieve the treatment goals outlined above. This is commonly done using a twice daily “mixed” insulin regimen (combinations of short- and intermediate-acting insulin given before breakfast and supper). If the diet is carefully adhered to, blood glucose levels are quite stable, and insulin dosage modifications are made every 1–2 weeks from a review of fingerstick blood glucose measurements obtained by the patient. Episodes of hyperglycemia are usually caused by temporary lapses in adhering to the prescribed diet.

Patients with near-normal blood sugar values in the first trimester may experience a modest reduction in insulin needs toward the end of this period (10–14 weeks), a time of particular vulnerability to severe hypoglycemic episodes¹³⁷ (see above). Subsequently, insulin requirements increase substantially in most patients before seeming to plateau in the third trimester at a level two- to threefold above doses used before pregnancy. A reduction in insulin need is sometimes noted in the week or two before term. The challenge of therapy is to modify the insulin dose in parallel with these alterations in insulin sensitivity.

Monitoring of Diabetes Control

At each outpatient visit, measurements of plasma glucose are obtained from the laboratory simultaneously with patient-determined estimates of capillary blood sugar to check the accuracy of the patient’s measurements. Blood sugars are monitored at home before each meal and at bedtime; at least twice weekly, the patient also measures values 1 hour after each meal. As noted above, in women with T1DM, the postprandial values may more closely parallel overall fuel delivery to the fetus and consequently may correlate better with birthweight than fasting values.^{161,162} However, we have found premeal blood sugar measurements to be of greater utility in recommending doses of Regular insulin. The limitation on the dose of Regular insulin that can be given before a meal is the nadir blood sugar level that will occur prior to the subsequent meal regardless of the magnitude of the between-meal peak. When postprandial hyperglycemia persists despite normalization of premeal levels, adjustments in meal size and/or frequency of feedings may be beneficial. We rely equally on postprandial and premeal glucose concentrations to assess adequacy of lispro doses. As mentioned above, when using lispro insulin, a premeal concentration that is higher than optimal can reflect either a need for a larger bolus of lispro insulin with the preceding meal or a need for the addition of a longer acting insulin.

Measurements of glycosylated hemoglobin are secured at the first visit during pregnancy and at 4–6-week intervals thereafter, since these supplement but do not replace the information derived from estimates of blood sugar. The initial value for glycosylated hemoglobin can often provide a useful index of the state of maternal fuel metabolism around the time of conception, implantation,

and organogenesis (see above), as well as a general indication of the risk of major congenital malformations, helping to guide decisions when elective abortion is a consideration. Measurements of fructosamine or glycosylated albumin may provide information analogous to that of glycosylated hemoglobin and may be desirable when the latter measure is unreliable (e.g., in the presence of hemoglobinopathy or hemolysis).

Patients are asked to test urine for ketones in the first morning urine specimen each day and at any time that premeal estimates of blood glucose exceed 200 mg/dL. These measurements are useful in detecting inadequate dietary intake, particularly of carbohydrate, and providing warning of impending metabolic decompensation. Monitoring urine glucose is unnecessary with the regimen outlined above.

Obstetric Surveillance

Patients are offered serum screening and a comprehensive ultrasound examination as surveillance for fetal anomalies. Serum screening with multiple analytes, performed between 15 and 20 weeks of gestation, typically includes maternal serum α -fetoprotein, estriol, and human chorionic gonadotropin. The α -fetoprotein portion can detect 80–90% of open neural tube defects and may also identify other defects such as gastroschisis and renal agenesis.¹⁷⁰ An abnormal pattern of the three analytes in combination with maternal age can detect approximately 60% of Down's syndrome cases¹⁷¹ and a similar portion of fetuses with trisomy 18.¹⁷² Regardless of serum screening results, the risk of diverse fetal anomalies in pregnancy complicated by diabetes mellitus warrants a comprehensive fetal anatomic survey by ultrasound. This is best performed after 18 weeks when the size of the fetus is sufficient to facilitate sonographic examination of all fetal structures. The sensitivity of ultrasound in detecting fetal abnormalities varies by anomaly. Gross defects such as hydrocephalus or omphalocele have very high detection rates, whereas others such as cardiac outflow tract anomalies are difficult to ascertain.¹⁷³

Ultrasound examinations during pregnancy permit confirmation of estimated due date as well as an assessment of the pattern of fetal growth. Confirmation of gestational age may be performed in the first trimester as early as convenient after 6 weeks of amenorrhea, at which time both determination of viability and accurate dating can be performed. The presence or absence of evolving fetal macrosomia can be determined by serial measurements of fetal head and abdominal size in conjunction with estimated fetal weight in the late second and third trimesters of pregnancy.^{119,125–127}

Intrauterine fetal death in late gestation was a relatively common event prior to the appreciation of the importance of good maternal metabolic control.⁸⁴ The etiology of this complication has never been established in human gestation, although data from animal models have suggested that sustained fetal hyperglycemia is associated with increased placental lactate production, increased fetal uptake of glucose and lactate, and stimulated fetal oxygen consumption, ultimately leading to fetal hypoxemia.^{174–176} The risk of fetal death may no longer be appreciably increased over background rates in pregnancies attended by excellent metabolic control, particularly in the absence of vascular disease or pregnancy complications.

However, different biophysical methods of fetal assessment may provide objective measures of reassurance.¹⁷⁷ The mainstay of fetal assessment remains the nonstress test. The observation of two or more accelerations of the fetal heart rate in response to spontaneous fetal activity during 20 minutes of continuous fetal heart rate

monitoring, designated a reactive test, is highly predictive of fetal well-being. An alternative modality is the biophysical profile by ultrasound, a technique that assesses fetal activity, fetal muscle tone, fetal breathing activity, and amniotic fluid volume, in addition to the nonstress test. A score of 2 is given for each positive finding, with a total possible score of 10; it is sometimes called the intrauterine Apgar score. We have utilized the nonstress test as our primary means of fetal surveillance, reserving use of the biophysical profile for assessment of a nonreactive nonstress test. Although weekly testing is usually initiated by 32 weeks of gestation, earlier and more frequent testing is indicated for pregnancies complicated by significant hypertension or other medical complications that may increase the risk of fetal death.

Meticulous surveillance for pregnancy complications is practiced at frequent prenatal visits, usually on a weekly basis after 30–32 weeks of gestation. It is generally accepted that the risk of pre-eclampsia is increased in women with diabetes mellitus, particularly for those with pre-existent vasculopathy. The traditional clinical criteria utilized for the diagnosis of pre-eclampsia are abrupt increase in blood pressure and appearance of proteinuria (>300 mg in 24 hours) in association with hyperuricemia. However, women with nephropathy may have a clinical course that can be easily confused with pre-eclampsia, including hypertension, which tends to worsen in the third trimester, increasing proteinuria presumed to be caused by the increased renal plasma flow of pregnancy, as well as hyperuricemia of uncertain origin. Making an accurate diagnosis in such patients requires close surveillance. The diagnosis of pre-eclampsia at or near term warrants consideration of immediate delivery. If pre-eclampsia is suspected in a preterm gestation, hospitalization is prudent for close observation of maternal and fetal status.

Delivery and Postpartum Care

Diabetic Aspects Medical management during either spontaneous or induced labor consists of monitoring blood sugar every 1–4 hours and continuous intravenous infusions of glucose at the rate of 5–10 g/h. Insulin is administered as needed, either as an intravenous infusion via a separate line at the rate of 0.01–0.04 U/h/kg actual body weight (i.e., 0.7–2.8 U/h in a 70-kg woman), or by subcutaneous injection of short-acting (Regular) insulin every 3–6 hours. The need for glucose and/or insulin should be based on the prevailing blood glucose, the time and nature of the last insulin injection, and the time of food ingestion prior to the onset of labor. The “exercise” effect of labor may enhance the rate of glucose utilization.¹⁷⁸ This effect may be partly modulated by the use of a continuous epidural anesthetic during labor. The therapeutic objective is to maintain circulating glucose in the physiologic range (70–120 mg/dL [3.9–6.7 mm/L]) throughout labor. In women who have been in good metabolic “control” throughout their third trimester, we have been unable to demonstrate a relationship between cord blood glucose at delivery and subsequent neonatal hypoglycemia, although such an association has been noted by others.¹⁷⁹

Elective cesarean sections should be scheduled early in the morning when possible. Neither glucose nor additional insulin is administered if blood sugar is in the range of 70–140 mg/dL (3.9–7.8 mm/L) immediately beforehand. Blood sugar values outside this range necessitate infusion of glucose, insulin, or both. Insulin requirement declines dramatically immediately following delivery (by as much as 75–90%), and the administered dose may have to be reduced temporarily to 25% or less of the total daily antepartum dose. Failure to observe this fall in insulin requirement may be the

earliest sign of a postdelivery infection or other obstetric complications. After a variable period, insulin requirements generally return to prepregnancy levels.

Opinions differ about the continuing use of CSII during labor or cesarean delivery. Some physicians feel strongly that the possibility of dislodging the tubing during the exertions of labor, or positioning of patients during delivery and possible alterations in subcutaneous insulin absorption should hypotension or significant hemorrhage occur, for example, speak strongly for use of intravenous insulin in these circumstances. However, patients frequently have a strong desire to continue the use of their insulin pump during delivery, and many physicians are comfortable with using CSII to manage blood glucose concentrations during this time. With either approach, the key to successful management is the frequent measurement of blood sugar concentration throughout the delivery process and post partum.

Women who wish to breastfeed are maintained at, or up to 300 calories above, their caloric intake before pregnancy. Because oral agents may be secreted in breast milk and cause hypoglycemia in the infant, their use is precluded in women with T2DM wishing to breastfeed. Women who do not plan to nurse are returned immediately to a diet appropriate for nongravid women (30–32 kcal/kg IBW [125–135 kJoule/kg]). All patients are encouraged to use the diabetes management skills they acquired during gestation.

Obstetric Aspects For the woman who has experienced an uncomplicated pregnancy, the goal of obstetric management is vaginal birth of a term infant. Cesarean delivery increases the risk of numerous maternal morbidities, particularly hemorrhage and infection, and should be reserved for standard obstetric indications. Unless spontaneous labor ensues, induction is planned at term (38–40 weeks) when the cervix is considered favorable. Elective preterm delivery is not warranted, as it is well accepted that the sequelae of prematurity are more prevalent in infants of diabetic mothers compared with age-matched infants of nondiabetic mothers. When a term delivery is anticipated, it is not necessary to employ amniocentesis routinely to document fetal pulmonary maturity. This procedure should be utilized if the estimated due date is uncertain or if delivery is performed at <38 weeks of gestation.

Infants are at increased risk of shoulder dystocia when there is an asymmetric increase in upper body size of the fetus relative to head size. This risk is approximately twofold higher for infants of diabetic mothers compared with normal infants at all birthweights.¹⁸⁰ Brachial plexus injury is an uncommon but serious complication of shoulder dystocia, usually presenting as Erb's palsy. Fortunately, >90% of Erb's palsies resolve over a period of time.¹⁸¹ That the risk of shoulder dystocia rises with increasing absolute fetal weight suggests that this complication may be obviated by planned cesarean delivery for selected patients. Various thresholds have been suggested, most commonly >4500 g in estimated fetal weight. However, formula-based estimates of fetal weight by ultrasound lack precision, with 95% confidence limits generally 15–20% of the estimated weight,¹⁸² and shoulder dystocia may still occur in an infant who is <4000 g actual birthweight. Although protocols may vary in different programs, a combination of ultrasound assessment of the fetus and clinical judgment in assessing the likelihood of an uncomplicated vaginal birth is warranted. Thus, one would not necessarily proscribe vaginal birth in a multipara with anticipated fetal macrosomia if she has had a previous uncomplicated delivery of an infant of similar birthweight.

Gestational Diabetes Mellitus

Definition and Magnitude of the Problem

GDM, defined as "carbohydrate intolerance of variable severity with onset or first recognition during pregnancy,"^{7–9} may complicate as many as 2–6% of pregnancies in North American centers, using National Diabetes Data Group (NDDG) criteria.^{158,183–186} Even higher figures have been reported when other diagnostic criteria for GDM have been used,^{185,187,188} and in some racial and ethnic populations incidences approaching 20% have been found.¹⁸⁹ It is thus >10 times more common than pregestational diabetes during pregnancy.

Studies in the 1970s and early 1980s found the risk of perinatal loss and neonatal morbidity to be increased when GDM was undetected or treated casually.^{190–193} However, recent studies have not found an increase in perinatal loss in GDM.⁸ This may reflect the concurrent overall improvement in obstetric practice or may be an effect of treatment. Women with GDM are often considered to be at "high risk," even when they are successfully managed with dietary intervention alone. Such a designation may in itself represent a form of intervention because it leads to more intensive obstetric supervision. In addition, home blood sugar monitoring and treatment with insulin if hyperglycemia persists are widely recommended.^{8,194} Thus, perinatal loss in GDM⁸ and the frequency of some neonatal morbidities (such as hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia) have decreased toward levels found in the general population^{195,196} (see Chap. 39). Despite such improvements in outcome, offspring of mothers with GDM remain at risk for fetal hyperinsulinism and attendant excess fetal size (macrosomia), which increases the likelihood of birth trauma and operative delivery,^{8,195} and, by implication, persistence of some degree of risk for long-range abnormalities.

Most studies have not found an increased risk of congenital anomalies in GDM. However, some association has been found in a few reports.^{197–200} This has been so among populations likely to harbor a substantial proportion of women with unrecognized pregestational T2DM. The above considerations provide incentives for the detection and treatment of GDM using current methods, as well as justification for clinical trials of earlier and more aggressive treatment.

Screening and Diagnosis

GDM is almost always asymptomatic, and selective screening for glucose intolerance on the basis of clinical "risk factors" and/or past obstetric history does not identify one-third to one-half of the affected subjects.^{8,184,185,201,202} Random estimates of blood glucose during prenatal visits have been advocated for the detection of asymptomatic glucose intolerance during pregnancy²⁰³; however, this approach also fails to detect a significant proportion of the cases,^{204,205} and measurements of glycosylated hemoglobin^{206,207} or fructosamine^{208,209} do not provide acceptable diagnostic sensitivity. Screening tests have been studied that assess maternal blood glucose responses to orally administered glucose polymers²¹⁰ or mixed meals.^{211,212} Measurement of second-trimester amniotic fluid insulin content, although it demonstrates reasonable sensitivity for early diagnosis of GDM,^{213,214} is costly and invasive and carries risk.

Participants in the Fourth International Workshop Conference on GDM modified previous recommendations that all women should undergo blood glucose testing for GDM because this approach may not be cost-effective in populations or clinics that

TABLE 38-2. Screening Strategy for Detecting Gestational Diabetes Mellitus (GDM)

Risk	Strategy
	GDM risk assessment should be ascertained at the first prenatal visit
Low	Blood glucose testing not routinely required if <i>all</i> of the following characteristics are present: Member of an ethnic group with a low prevalence of GDM No known diabetes in first-degree relatives Age < 25 years Weight normal before pregnancy No history of abnormal glucose metabolism No history of poor obstetric outcome
Average	Perform blood glucose testing at 24–28 weeks using either Two-step procedure: 50-g glucose challenge test (GCT) followed by a diagnostic oral glucose tolerance test in those meeting the threshold value in the GCT (see text for details) One-step procedure: diagnostic oral glucose tolerance test performed on all subjects
High	Perform blood glucose testing as soon as feasible, using the procedures described above. If GDM is not diagnosed, blood glucose testing should be repeated at 24–28 weeks, or at any time a patient has symptoms or signs suggestive of hyperglycemia

Reproduced from Metzger *et al.*⁸

include a large proportion of subjects at low risk for GDM⁸ (Table 38-2). It is recommended that risk assessment be carried out as soon after registration for prenatal care as feasible. To be considered low risk, subjects must have *all* of the following characteristics: member of racial/ethnic group with a low prevalence of GDM; age < 25 years; normal weight; no family history of diabetes; and no personal history of abnormal glucose metabolism or poor obstetric outcome. Those that are designated high risk for GDM should undergo blood glucose testing early in pregnancy. If GDM is not found, testing should be repeated at 24–28 weeks or at any time the patient develops symptoms suggestive of hyperglycemia. All others should be screened at 24–28 weeks of gestational age.⁸

In North America, a two-step screening-diagnostic strategy is most commonly applied. Subjects receive a 50-g oral glucose challenge (GCT) given without regard to time of the last meal or time of day, and venous plasma glucose is measured 1 hour later. A plasma glucose value ≥ 140 mg/dL (7.8 mmol/L) is considered positive. Using this threshold, 14–16% of pregnant women at our center screen positive and require further testing.¹⁸⁶ The yield of GDM can be increased by approximately 10% if the screening threshold is reduced to 130 mg/dL (7.2 mmol/L), which might be considered trivial from the epidemiologic cost/benefit perspective in that it increases the proportion who require further testing to 23–25% of women.^{185,186,215} Although it is convenient and rapid, measurement of capillary blood sugar with the use of reagent strips and portable meters is not sufficient for this purpose. Intratest variability of

10–15% with such methods lowers both the sensitivity and specificity of the procedure.²¹⁶

A positive screening for GDM is followed by an oral glucose tolerance test (OGTT) for definitive diagnostic evaluation. We use a 100-g load for such diagnostic OGTTs and interpret the venous plasma glucose results according to the criteria of O'Sullivan and Mahan.¹⁸³ These criteria for the diagnosis of GDM were originally developed to identify a population of pregnant women who were at high risk for developing diabetes mellitus post partum.¹⁸³ In the absence of criteria based on the specific relationships between hyperglycemia and adverse perinatal outcome, the work of O'Sullivan and Mahan has been used as the basis of the criteria recommended by the NDDG,⁷ the GDM Workshop Conferences,⁸ and the American Diabetes Association⁹ because it represents a well-designed, population-based study. The NDDG extrapolated values for Auto-Analyzer-measured plasma glucose from the criteria originally derived from whole blood glucose determination,⁷ and Carpenter and Coustan²¹⁷ later adjusted the values to approximate more closely the values obtained with the glucose oxidase enzymatic assay of plasma or serum glucose (Table 38-3). Use of the criteria of Carpenter and Coustan labels nearly 50% more subjects as GDM than is the case when the NDDG criteria are applied.^{186,188} Data from several populations now indicate that the additional cases diagnosed by Carpenter-Coustan criteria have a risk of perinatal morbidities similar to those of women diagnosed with the NDDG criteria.^{188,218–220} Thus, the Fourth International Workshop Conference

TABLE 38-3. Diagnosis of Gestational Diabetes Mellitus (GDM): 100-g Oral Glucose Tolerance Test*

	O'Sullivan-Mahan ¹⁸³ Whole Blood Somogyi-Nelson (mg/dL [mmol/L])	NDDG ⁷ Plasma Auto-Analyzer (mg/dL [mmol/L])	Carpenter-Coustan ²¹⁷ Plasma Glucose Oxidase (mg/dL [mmol/L])
Fasting	90 [5.0]	105 [5.8]	95 [5.3]
1 hour	165 [9.2]	190 [10.6]	180 [10.0]
2 hour	145 [8.1]	165 [9.2]	155 [8.6]
3 hour	125 [6.9]	145 [8.1]	140 [7.8]

The 100-g oral glucose tolerance test is performed in the morning after an overnight fast of at least 8 hours, but not more than 14 hours, and after at least 3 days of unrestricted diet (≥ 150 g carbohydrate/day) and physical activity. The subject should remain seated and should not smoke throughout the test. Two or more of the venous plasma concentrations must be met or exceeded for a positive diagnosis.

on GDM concluded that the Carpenter-Coustan criteria may be recommended for the interpretation of a 100-g OGTT in pregnancy.⁸

Values for interpretation of 75-g OGTTs have been defined in several study populations in the United States, Europe, Brazil, and Australia.⁸ As a general statement, it can be said that the various cutoff values that have been recommended for interpretation of the 75-g OGTT do not differ greatly from the Carpenter and Coustan criteria for the 100-g OGTT. However, studies in which perinatal outcome has been evaluated in large numbers of pregnancies meeting the 75-g OGTT criteria for GDM are lacking. It is anticipated that the currently ongoing study funded by the National Institutes of Health and the American Diabetes Association (Hyperglycemia and Adverse Pregnancy Outcome) will provide data from which criteria can be derived that are based on the relationship between degree of hyperglycemia and risk of adverse perinatal outcome. Therefore, at this time, we suggest that clinics that have established programs for GDM detection and diagnosis continue to use the diagnostic procedure with which they are familiar.

Etiology and Pathogenesis

Although all cases of GDM share the fact that they are first recognized in association with the physiologic insulin resistance of pregnancy, they are also characterized by substantial phenotypic and genotypic heterogeneity.^{158,221} The severity of the carbohydrate intolerance at the time of diagnosis represents one form of phenotypic heterogeneity, and it has served as the basis for the use of FPG to subclassify GDM (Table 38-1). It is also an important predictor of risk for progression to diabetes outside of pregnancy.¹⁸³ There is also appreciable heterogeneity with regard to age and weight, and it has been long appreciated that women with GDM tend to be older and heavier than unselected "populations" of pregnant women. Finally, GDM is heterogeneous with respect to insulin resistance and β -cell function.

Catalano and coworkers⁶⁷ have performed important serial studies of carbohydrate metabolism starting before pregnancy (Fig. 38-5). Women with previous GDM but normal glucose tolerance were insulin-resistant compared with age- and BMI-matched controls. During the first trimester, the GDM group showed a small increase in insulin sensitivity, whereas the controls showed a small decline. In late gestation, the normal subjects had developed marked insulin resistance and the GDM group became more insulin resistant than before gestation. Although both groups were very insulin-resistant in late pregnancy, the women with GDM were on average more insulin-resistant, with considerable overlap. Others have also found somewhat greater insulin resistance in GDM than in normal pregnancy.^{26,222} In the Catalano study and in others, women with normal carbohydrate metabolism were found to compensate for the insulin resistance in late gestation with augmentation of β -cell function that was appropriate for the level of insulin resistance. By contrast, those with GDM fail to increase β -cell function adequately and show a large defect in first-phase insulin secretion when challenged with oral or intravenous glucose.^{22,26,89,158,221}

On the basis of clinical features, GDM has been classically considered to be a variant of T2DM. However, examinations for certain genetic "markers" suggest that there may be appreciable genotypic heterogeneity in GDM. Some patients exhibit autoimmune phenomenon,¹⁵⁸ with glutamic acid decarboxylase (GAD)²²³ or islet cell antibodies^{158,224,225} found with variable prevalence depending on the population studied and the methods used. This is more common in Scandinavian countries, where there is greater prevalence of T1DM.²²⁵ These findings suggest that a

small proportion of patients with GDM may have evolving T1DM with first appearance in pregnancy. Efforts to identify the specific cases prospectively may be justified in populations with a higher prevalence of T1DM.

Racial/ethnic group differences in prevalence of GDM have been observed that are not fully accounted for by differences in maternal age or obesity.^{186,189,226} A small number of women with GDM have been found to have maturity-onset diabetes of the young (MODY) diabetes or defects in mitochondrial DNA. For most women with GDM, however, the specific mechanisms for genetic predisposition remain to be defined.

Management

Diet

Medical nutritional therapy is the cornerstone of management and is implemented as soon as possible after the diagnosis of GDM is established. At Northwestern University, dietary recommendations in the latter half of pregnancy are the same for GDM as in normal pregnancies and in pregnancies complicated by pregestational diabetes (see discussion above).

Insulin

The precise place for insulin in the therapy of GDM is not fully crystallized.^{8,194,227} In patients with fasting hyperglycemia diagnostic of diabetes (i.e., FPG $\geq$ 126 mg/dL [7.0 mmol/L]), there is little, if any controversy.⁸ At Northwestern University, insulin treatment is started as soon as the diagnosis of GDM is confirmed in these subjects because neonatal risks equal those for patients with pregestational diabetes. Insulin therapy is instituted in all gravidas with GDM and FPG $\geq$ 105 and $<$ 126 mg/dL (5.8–7.0 mmol/L) persisting on two successive determinations following a brief trial of dietary therapy. At many centers, insulin therapy is initiated if FPG exceeds 94 mg/dL (5.2 mmol/L), the revised upper limit of normal adopted by the Fourth International Workshop Conference on GDM.⁸ Many¹²⁶ feel that a number of GDM mothers with FPG in the range of 95–104 mg/dL have unaffected offspring. They have suggested that pending the results of the ongoing Hyperglycemia and Adverse Pregnancy Outcome study mentioned above, one should not extend the criteria for initiation of insulin therapy to include this subgroup of subjects.

The use of insulin therapy is more controversial in women with GDM in whom FPG is consistently below the upper limits of "normal," i.e., $<$ 95 mg/dL (5.3 mmol/L).^{228,229} Most patients with GDM fall into this category, and some of their offspring may be at increased risk for macrosomia^{88,118,158} and potentially other perinatal difficulties as well as long-range developmental changes.^{230–235} Accordingly, some have recommended therapy with insulin in *all* women with GDM who are over 25 years of age, or have offered insulin therapy as a prophylactic option against the possibility of macrosomia in all GDM pregnancies.^{236,237} Others have applied strict goals for glycemic control that have resulted in the use of insulin to treat more than half²³⁸ or more than 85%¹⁹⁶ of their subjects with mild GDM. Such aggressive treatment has been shown to reduce average birthweight,^{227,228} but the cost/benefits in terms of neonatal morbidity, childhood obesity, and glucose tolerance have not been demonstrated.⁸ In the absence of such information, one should restrict the use of insulin treatment in GDM with FPG $<$ 105 mg/dL (5.8 mmol/L), to those with 1-hour post breakfast plasma glucose $\geq$ 140 mg/dL (7.8 mmol/L) and persisting despite diet therapy.

Defining the optimal criteria for insulin treatment solely by blood glucose values is problematic because other metabolic fac-

tors²³⁹ and maternal nutrients in addition to glucose probably impact on fetal growth.^{88,118,157} Criteria other than maternal blood sugar levels to determine the need for insulin therapy are being investigated. In uncontrolled trials, Weiss and colleagues^{240,241} have reported good fetal outcomes when elevated amniotic fluid insulin levels (which reflect fetal hyperinsulinemia) have been used to determine the need for insulin therapy. Fetal ultrasound to measure shoulder soft tissue²⁴² or abdominal circumference^{126,229,243} have been employed in an effort to select pregnancies with mild hyperglycemia at highest risk for macrosomia, and thus insulin treatment. It is to be hoped that controlled clinical trials designed to assess all these issues and strategies (perhaps on a multicenter basis) will provide the observations necessary for more definitive recommendations.²⁴⁴

When insulin is used, doses ranging from 0.5 to 1.4 U/kg of body weight/day are required to maintain fasting and premeal glucose values of 65–85 mg/dL (3.6–4.7 mmol/L) and postprandial values of <140 mg/dL (7.8 mmol/L). A twice-daily “mixed” insulin regimen is usually employed, although multiple injections may be used. Sulfonylurea drugs, as a class, have been avoided during pregnancy because some of them have been shown to cross the placenta, stimulate fetal insulin secretion, and promote neonatal hypoglycemia. Recently, clinical data have been presented by Langer and coworkers²⁴⁵ indicating that one of these agents, glyburide, is devoid of these properties and is as efficacious as intensive insulin therapy in controlling maternal blood glucose concentration and preventing fetal and neonatal effects of GDM. If these findings are confirmed, glyburide may become an important alternative for the treatment of GDM.

Exercise

Cardiovascular fitness training is known to increase insulin sensitivity and glucose disposal by recruitment of glucose transporter proteins, and it is often used in the treatment of suitable patients. In pregnancy, concerns about increasing uterine contractility, IUGR, prematurity, fetal bradycardia, and ketonuria have overridden the potential beneficial effects of strenuous exercise.^{246,247} Two studies employing moderate exercise regimens in GDM, using either arm ergometry²⁴⁸ or a recumbent bicycle,²⁴⁹ have found them to be safe and effective in reducing fasting and postprandial glucose to a modest extent. In another trial that explored the effects of moderate exercise on glycemic control, no beneficial response could be demonstrated.²⁵⁰ Further studies of exercise in GDM are in progress.

Monitoring Carbohydrate Metabolism

Patients with GDM should monitor urinary ketones before breakfast and supper to detect possible deficiencies in dietary carbohydrate. Many women on dietary therapy choose to monitor capillary blood glucose values as well. At each outpatient visit, fasting and 1-hour post-breakfast plasma glucose measurements should be obtained to help determine the need for insulin therapy. All patients who are treated with insulin should monitor capillary blood sugar before meals (4×/day) at home as a guide to making insulin dosage adjustments on a weekly basis in consultation with the physician or nurse practitioner. It is also recommended that patients monitor postprandial blood glucose levels on at least 2 days a week. Monitoring postprandial blood sugar exclusively to guide the selection of insulin doses has been claimed to be superior to a reliance on testing blood glucose concentrations before meals.²⁵¹ One approach may not be inherently superior to the other, provided that appropriate target values are set and pursued vigorously. To assess

the accuracy on an ongoing basis, patients who perform fingerstick blood glucose testing should have plasma glucose measurements obtained at each prenatal visit to compare with a simultaneously obtained estimate of capillary blood glucose concentration. Some self-monitoring blood glucose systems may consistently over- or underestimate plasma glucose by as much as 10–15%. This must be determined on an individual basis and taken into account when insulin doses are modified.⁸

POSTPARTUM FOLLOW-UP

Carbohydrate Metabolism

The diagnosis of gestational diabetes carries significant implications for long-term maternal health. During pregnancy, one cannot distinguish with certainty between evolving T1- or T2DM and transitory glucose intolerance that will subside post partum. Postpartum reclassification and long-term follow-up are therefore essential (Table 38-1). Within the first year post partum, a significant proportion of our patients with GDM display impaired glucose tolerance or diabetes mellitus by NDDG criteria.⁷ For women in whom FPG during pregnancy is elevated to levels that are diagnostic of diabetes, the incidence is 75–90%.^{252,253} It is likely that in some of these, abnormalities in glucose tolerance antedate pregnancy.^{252,254} Although their testing procedures differed somewhat, workers from Los Angeles,^{227,255} East Germany,²⁵⁶ Australia,¹⁹⁸ and Saudi Arabia²⁵⁷ have also reported high incidence of impaired glucose tolerance during the first 1 or 2 years of postpartum follow-up. Many others have shown that GDM, based on a variety of diagnostic criteria, identifies women at high risk for the later development of diabetes mellitus and that the incidence increases progressively with time from the index pregnancy.^{183,198,199,258–263}

Certain genetic and phenotypic characteristics that are observable during pregnancy convey a higher risk for postpartum glucose intolerance.^{227,252,253,255,258,262–264} These include relative insulinopenia; severity of glucose intolerance at diagnosis; obesity; early gestational age at diagnosis; racial/ethnic origin (increased in Hispanics); and family history of maternal diabetes. Using multiple logistic regression, the independent associations between these factors and diabetes mellitus developing early post partum and up to 5 years later were examined.^{252,253} Relative deficiency (lower basal insulin levels and blunted acute-phase insulin response to oral glucose) and the severity of antepartum hyperglycemia (fasting and 2-hour values) were independently associated with the presence of diabetes mellitus in the early postpartum period. Obesity (with its associated increased insulin resistance) and blunted integrated insulin responses (area under the curve) were also independent variables in those who developed diabetes mellitus up to 5 years post partum. The other prognostic factors (early gestational age at diagnosis, racial/ethnic origin, and family history of maternal diabetes) are probably mediated through one or more of the independent factors noted above.

Because of the risks outlined above, all women with GDM should receive an assessment of glucose tolerance within 6–12 weeks after delivery. Initial evaluation should be either the measurement of fasting plasma glucose concentration or a 75-g OGTT. Results should be interpreted according to the American Diabetes Association Expert Committee on the Diagnosis and Classification of Diabetes Mellitus.⁹ Those who manifest persistent glucose intolerance (impaired fasting glucose, impaired glucose tolerance test, or T2DM) should receive appropriate counseling and/or therapy. At the time of any subsequent pregnancy, their

status should be classified as indicated in Table 38-1. Kjos and coworkers^{227,255,265-267} have identified postpartum characteristics that predict risks of progression to diabetes at the time of postpartum evaluation. Risk factors include higher level of glycemia at initial postpartum evaluation, further weight gain, use of progestin-only oral contraceptive pills, and subsequent pregnancy.

Individuals with a normal postpartum FPG or OGTT need annual fasting or postload glucose testing and should be aware that glucose intolerance, although not invariable, will probably recur during any future pregnancy, if not before. As yet, only limited data are available from long-term intervention efforts designed to mitigate the development of diabetes under nongravid conditions. Nonetheless, it seems prudent to advise patients to maintain ideal body weight, to exercise regularly, and to avoid the use of progestin-only oral contraceptives, thiazides, niacin, and oral corticosteroids if possible. Clinical trials that include evaluation of pharmacologic agents to "prevent" or delay the development of diabetes in individuals at high risk, including women with previous GDM, are now being carried out. One trial, the Diabetes Prevention Program, includes intensive lifestyle intervention and metformin treatment arms.²⁶⁸ It will conclude in the year 2002. Another, in which the insulin-sensitizing drug troglitazone was used, has provided encouraging preliminary results.²⁶⁹ Use of the agent was discontinued when the drug was removed from sale; however, the rate of conversion to diabetes was significantly reduced during the 2 years of exposure to troglitazone. It is not yet known whether this effect persisted after discontinuation of the drug.

Contraception and Other Considerations

The postpartum period is an ideal time to practice preconception counseling, since a recently parous woman, who is of proven fecundity, is likely to conceive again. Behaviors that will promote good health should be discussed, including issues such as weight loss and exercise. These may not have been appropriate interventions to initiate during pregnancy. The benefits of good metabolic control lifelong, especially prior to a planned pregnancy, should be reinforced.²⁷⁰

After Pregestational Diabetes

For the woman with T1DM, there are few substantive reasons for selecting one contraceptive method over another, and the woman's desires should be paramount in the decision. Although barrier methods (condom, diaphragm) might be considered ideal choices because of the absence of systemic effects and paucity of side effects, these methods are attended by a failure rate of at least 5% per woman-year.²⁷⁰ Copper-containing intrauterine devices are equally effective and safe in women with diabetes mellitus but should be reserved for those in a mutually monogamous relationship due to the risk of pelvic infection.

Although the early generations of combination oral contraceptives incurred risks of adverse metabolic effects (e.g., reduced carbohydrate tolerance, lowering of high-density lipoproteins), contemporary formulations have a severalfold reduction in hormonal potency accompanied by an attenuation of metabolic side effects.²⁷⁰ Preparations containing norethindrone as the progestin appear to have fewer metabolic effects than levonorgestrel. However, the low serum levels manifested with levonorgestrel implants have been shown to effect only minor metabolic changes in nondiabetic women, with excellent protection against pregnancy for up to 5 years. Newer progestins of increased selectivity (e.g., deso-

gestrel) have shown promise of minimal metabolic effects. The use of hormonal contraceptives in women with diabetic vasculopathy remains controversial. However, documented cardiovascular risks of hormonal contraceptives in nondiabetic women, particularly myocardial infarction, have been linked to concurrent smoking and higher dose formulations, and there are no adequately controlled studies in women with diabetes mellitus. Thus, the benefit of excellent contraceptive efficacy must be weighed against theoretical risks.

After GDM

Although contraceptive counseling is similar to that for women with T1DM, there is the concern that oral contraceptives may result in a recrudescence of carbohydrate intolerance.^{266,267,270} This concern has not been borne out with use of contemporary low-dose formulations. However, progestin-only oral contraceptive agents have been associated with some increased risk of diabetes after GDM.^{266,267} It is prudent to document normal postpartum carbohydrate tolerance before initiating any hormonal contraceptive and to recommend regular surveillance at 6-12-month intervals.

Acknowledgments The authors are grateful to their many collaborators in the Departments of Medicine, Obstetrics, and Pediatrics who have contributed to The Northwestern University Diabetes in Pregnancy Center studies that are cited in this chapter. We thank the nursing staff of the Clinical Research Center at Northwestern Memorial Hospital for help in the testing and clinical management of a number of our patients. This work was supported in part by NIH research grants DK 10699, HD 11021, HD 19070, HD 62903, HD 23141, and RR-48; by Training Grant DK 07169 from the United States Public Health Service; and by a grant from the Ronald McDonald Foundation.

Boyd E. Metzger

PREGNANCY AS A "TISSUE CULTURE EXPERIENCED"

The importance of the intrauterine environment as a determinant of metabolic function throughout the life span is being increasingly recognized.¹ The late Jorgen Pedersen was the first to propose a mechanism whereby maternal fuels may exert a direct effect on the fetus.² In attempting to explain the large babies that are sometimes seen in pregnancies complicated by diabetes, he advanced the hyperglycemia-hyperinsulinism hypothesis. Therein he postulated that more maternal glucose gains access to the fetus whenever maternal insulin is inadequate, and that this extra glucose stimulates insulin release in the fetus and thereby produces an increase of fetal mass.^{2,3} Pedersen's hypothesis gained increased credence with the demonstration that the placenta is impermeable to insulin⁴ so maternal and fetal insulin (and the metabolic effects of such insulin) are separately compartmentalized.

Subsequent work demonstrated that *all* maternal fuels may be maladjusted in even the mildest forms of gestational diabetes.^{5,6} Thus multiple fuels may contribute to the enhanced availability of building blocks for fetal growth and the premature development and functional activation of fetal B-cell secretion that Pedersen postulated.^{2,5} Accordingly, the Pedersen hypothesis can be modified to include *maternal fuels besides glucose* that are also regulated by maternal insulin^{5,7} (Fig. 39-1). It is then expected^{5,8} that the growth enhancing actions of these fuels would affect fetal insulin-sensitive structures⁹⁻¹³ to a greater degree than structures which are relatively insulin-insensitive.¹¹⁻¹³ Thus the hallmark of diabetic macrosomia should be *asymmetrical* growth in which weight (as an index of adipose stores) would be affected more than biparietal diameter (as an index of cerebral growth) or length (as an index of skeletal growth).^{5,14,15} Thus pregnancy can be likened to a "tissue culture experience" since most of these fuels cross the placenta in concentration-dependent fashion (see Chap. 38)⁷ so their concentrations in the maternal circulation may determine the quantitative as well as qualitative characteristics of the "incubation medium" in which the conceptus develops.^{5,8}

In support of the "tissue culture" formulation and the modified Pedersen hypothesis, it has been shown that even the most minor abnormalities in glucoregulation during pregnancy (i.e., gestational diabetes mellitus class A1; see Chap. 38) are attended by (1) enhanced functional maturation of the β -cells in fetal islets

(as judged *in utero* by increased levels of immunoreactive insulin in amniotic fluid during late pregnancy,¹⁵⁻¹⁸ or at birth by elevated C-peptide/glucose ratios in cord blood^{15,17,18}); and (2) relatively greater rates of growth in insulin-sensitive than in insulin-insensitive structures (as judged by serial ultrasound patterns *in utero*¹⁵ or weight/length relationships at birth^{15,18}). In studies of body composition, Catalano and colleagues have demonstrated increased fat mass in offspring of mothers with gestational diabetes, even at birthweights similar to those of offspring of mothers with normal glucose tolerance.¹⁹ More importantly, these developmental changes can be correlated directly with maternal plasma levels of amino acids and FFA, as well as glucose, during the second or third trimester.^{5,20-22} Thus all maternal fuels may be implicated in the altered developmental timetables which appear to affect certain structures more than others, especially in late fetal life.

CLINICAL FEATURES OF SPECIFIC MORBIDITIES

The morbidities in the infants of diabetic mothers (IDMs) are understood most readily in the context of the above alterations in the delivery of multiple building blocks from mother to conceptus and the attendant premature morphological and functional development of the B cells of the fetal pancreas leading to hyperinsulinism. Conversely, extensive clinical experience has documented that both the frequency and the severity of neonatal morbidities are reduced substantially when diabetes mellitus is well controlled throughout gestation.^{23,24} However, because of the variability in quality of antepartum metabolic control that is attained, the medical team attending the delivery on an infant of a diabetic mother must remain prepared to deal with a wide spectrum of neonatal morbidities.

Unexplained Fetal Loss During Late Gestation

In the past, difficulties in pinpointing the cause(s) of this major perinatal complication of diabetes in pregnancy or identifying individual pregnancies at highest risk contributed heavily to the practice of arbitrary early delivery. Improvements in metabolic control of diabetes throughout pregnancy and in obstetric assessment of fetal well-being (see Chap. 38) have markedly reduced the frequency of this dreaded complication. Studies with animal mod-

FIGURE 39-1. Effect of maternal fuels on fetus development. The classical "hyperglycemia-hyperinsulinism" hypothesis of Pederson^{2,3} has been modified^{4,8} to include the contributions of other maternal fuels beside glucose that are also responsive to maternal insulin. All of these can influence the growth of the fetus and the maturation of fetal insulin secretion. Within this formulation, growth will be disparately greater in insulin-sensitive than insulin-insensitive tissues in the fetus.

els have also provided important clues regarding pathophysiology. Philipps and coworkers²⁵⁻²⁷ have used the chronically catheterized fetal sheep to demonstrate that sustained fetal hyperglycemia is associated with stimulation of fetal oxygen consumption,²⁶ increased fetal uptake of substrates (glucose and lactate), and placental lactate production,²⁷ and can result in fetal hypoxia with consequent metabolic acidosis and fetal demise.²⁵ While this pathophysiological sequence has not been proven in humans, it could explain some of the increased risk of intrauterine fetal death and poor ability to tolerate labor which remain major concerns when pregnancy complicated by diabetes mellitus has not been optimally controlled.

Birth Defects

Experimental, clinical, and epidemiologic studies indicate that increased risks of congenital malformations and spontaneous abortions in pregnancies complicated by diabetes are linked to disturbances in maternal metabolism around the time of conception. As summarized in Chap. 38, data currently available indicate that predisposition to congenital malformations is unlikely to be explained by a single circulating metabolic agent, but instead may be multifactorial in origin. A number of factors that might mediate "metabolic teratogenesis" have been described (myoinositol depletion, polyol accumulation, arachidonic acid deficiency, free oxygen radical generation). However, alterations in the concentrations of metabolic fuels singly or in combination, do not appear to directly account for the potent dysmorphic actions of serum from pregnant diabetic women or diabetic animals.

Although neither the precise time nor duration of exposure to an abnormal metabolic environment necessary for adverse events to develop in the human embryo has been pinpointed, there has been substantial progress towards their prevention. When counseling and improved control of diabetes mellitus are initiated prior to conception, several groups have reported rates of major congenital malformations not higher than expected in the general obstetrical population. Unfortunately, in the United States, the majority of pregnant women with diabetes are not enrolled in regimens of tight metabolic control prior to conception. Consequently major congenital malformations are still commonly encountered.

Neonatal Care of IDMs with Major Malformations

Infants of diabetic mothers (IDMs) with major malformations should be evaluated as if the cause of their malformations might not be maternal diabetes (i.e., fuel-mediated teratogenesis is best considered an etiology of exclusion). For this reason, a genetics consultation might be warranted as chromosomal analysis and other genetic studies may be indicated. In addition, depending on the type of malformation and the findings of a careful physical examination, studies of other organ systems (e.g., ultrasound imaging of the heart, kidneys, etc.) may be important because an anomaly of one organ system may be associated with one in another system. It is appropriate to perform an imaging study of the brain to check for any gross abnormalities. With completion of this evaluation, appropriate plans for care can be implemented.

A multidisciplinary approach to support the family is critically important to address their emotional, social, and financial needs. Every effort must be made to explain the nature of the malformation and treatment options. If necessary, long-term care plans must be devised and all aspects of discharge planning arranged well before the infant leaves the hospital.

Disturbances in Fetal Growth

As noted earlier, alterations in maternal metabolic fuels have a direct influence on the functional state of the fetal pancreatic B cells and the regulation of fetal growth. Normalization of the metabolic milieu throughout pregnancy is the key to prevention of fetal hyperinsulinism and diabetic macrosomia. This topic is explored in depth in Chap. 38. Despite the greater insight into the regulation of intrauterine growth, the incidence of large babies has tended to increase in recent years, especially in type 1 diabetes mellitus (T1DM). Better control of diabetes in early pregnancy (thus avoiding early growth retardation) and discontinuation of routine delivery before term may account for the rarity of intrauterine growth restriction and the increased prevalence of macrosomia. Rates of macrosomia as high as 30-40% have been reported in recent years, and the risk of birth trauma (shoulder dystocia) associated with truncal adiposity that is typical of diabetic fetopathy has increased. Thus delivery and neonatal care of IDMs continue to present challenges in perinatal management.

Hypoglycemia

The normal human fetus at term is sufficiently metabolically mature to adapt to extrauterine life. It has adipose tissue, triglyceride stores, hepatic glycogen stores, and gluconeogenic capabilities. These depots interact in homeostatic fashion at birth as catecholamine and glucagon secretions surge while insulin secretion diminishes. The integrated relationships favor the production of endogenous glucose so the neonate can adapt to the sudden cessation of maternally-derived glucose.²⁸⁻³⁰ Symptomatic hypoglycemia supervenes whenever this endogenous production of glucose is insufficient to sustain the fuel requirements of the brain.

While cerebral uptake of glucose at a given concentration of circulating glucose can be somewhat variable, determinations of plasma or blood glucose concentrations offer the only clinical means of assessing glucose delivery. From the screening of a large number of infants during the neonatal period, plasma glucose concentrations of 1.4–1.7 mmol/L have often been used as benchmarks of neonatal hypoglycemia. However, it has been suggested that glucose provision to tissues may not always be adequate when plasma glucose concentrations are at these statistically-derived lower limits, and that a value of 2.2 mmol/L is more consistent with safe levels of glucose flux.³¹ Within that framework, approximately 20–25% of all IDMs experience neonatal hypoglycemia, usually during the first 4–6 hours. It must be emphasized that the level of plasma glucose concentration corresponding to inadequate provision of glucose to the brain is difficult to assess and that the duration of hypoglycemia necessary to damage the central nervous system has not been determined.³² Within this framework, transient or persistent hypoglycemia (defined as two or more plasma glucose concentrations <1.7 mmol/L in the first 48 hours of life), when di-

agnosed and treated does not adversely affect cognitive development in IDMs at 2–5 years of age. This emphasizes the importance of optimizing maternal and neonatal care.³³

The potent role of hyperinsulinism in neonatal hypoglycemia has been verified by isotopic estimates of glucose flux in newborn IDMs.^{34,35} Additionally, the hyperplastic^{36,37} and hyperfunctioning^{15,17,18,38-42} islets of the IDM respond to acute glycemic challenge with brisk insulin secretion rather than the blunted insulin release that constitutes the normal neonatal pattern (Fig. 39-2). The hyperinsulinemia limits hepatic glucose production directly and also enhances tissue uptake of glucose. Hepatic glucose production also may be compromised by an apparent inhibition of the induction of such key gluconeogenic enzymes as liver phosphoenolpyruvate carboxykinase.⁴³ Insulin has been shown to block the transcription of mRNA for phosphoenolpyruvate carboxykinase.⁴⁴

The clinical manifestations of neonatal hypoglycemia may vary substantially. Thus hypoglycemic infants may remain asymptomatic or become limp, obtunded, jittery, tremulous, sweaty, or cyanotic. Seizures may develop and profound hypoglycemia may cause brain damage. If hypoglycemia is prolonged, myocardial contractility diminishes and congestive heart failure may develop. Accordingly, all IDMs should be screened for hypoglycemia hourly until the first full feeding and at frequent intervals during the first 24 hours of life. If glucose oxidase-impregnated reagent strips are used to screen for neonatal hypoglycemia, abnormal values must be confirmed with actual plasma or blood determinations in the laboratory. While awaiting laboratory documentation, asymptomatic infants who are capable of oral feeding may receive glucose solution to correct hypoglycemia. Symptomatic infants should be treated with 10–15 mL/kg of 10% glucose solution rather than with mor-

FIGURE 39-2. The effect of intravenous glucose on plasma C peptide in the newborn. The secretory response to glycemic challenge in newborns of mothers with normal carbohydrate metabolism (solid circles) is sluggish, characteristic of relatively immature islet function. By contrast, the response is brisk and greater in the IDM (open circles), reflecting earlier maturation of stimulus-secretion coupling in fetal islets. (Reproduced from Phelps et al.⁴¹)

concentrated solutions of glucose, that carry the risk of precipitating greater acute insulin release. Follow-up estimates of plasma or blood glucose must always be secured to assure adequacy of therapy and to screen for potential recurrence of hypoglycemia.

Respiratory Distress Syndrome (RDS)

Infants of diabetic mothers have been considered at increased risk for the development of RDS.⁴⁵ However, much of this risk may have been eliminated by the recent emphasis on tight control of maternal metabolism (see Chap. 38). The inordinate susceptibility of the offspring of the poorly regulated diabetic mother to RDS has been linked to a delay in the processes leading to fetal lung maturation. Hyperglycemia as well as hyperinsulinism have been implicated⁴⁶ due to their inhibitory effects on surfactant synthesis by the pulmonary type II cell. The advent of exogenous surfactant therapy has greatly improved the ability to treat RDS.

Hypocalcemia and Hypomagnesemia

Total plasma or ionized calcium concentrations should be measured after birth in both sick and healthy IDMs since significant hypocalcemia may develop in the neonatal period, even when the effects of prematurity and birth asphyxia are taken into consideration.⁴⁷ Parathyroid hormone secretion in IDMs has been reported to be blunted during the first 4 days of life^{48,49} compared to infants of normal mothers. Hypomagnesemia which limits parathyroid hormone secretion even in the presence of hypocalcemia may be an important contributing factor.⁵⁰ The hypomagnesemia develops in women with diabetes as a result of increased renal losses associated with glucosuria. This in turn causes fetal and neonatal hypomagnesemia.

Clinical signs of hypocalcemia include jitteriness, twitching, or seizures; arrhythmias may also occur. It should be remembered that the neonate may not develop the characteristic prolongation of the QT interval associated with hypocalcemia in the adult. Respiratory distress syndrome and birth stress also increase the risk of hypocalcemia.

Symptomatic hypocalcemia should be treated with an infusion of 10% calcium gluconate (2 mL/kg body weight over 5–10 minutes). During infusion, monitoring with an electrocardiogram is important. IDMs may require from 75–200 mg/kg elemental calcium/day administered either enterally or parenterally. IDMs who are hypocalcemic on the basis of hypomagnesemia will not become normocalcemic until their hypomagnesemia is corrected. A 50% solution of magnesium at a dose of 0.25 mg/kg may be administered intramuscularly to correct hypomagnesemia.

Polycythemia/Hyperviscosity

IDMs are at increased risk for polycythemia and for the development of the neonatal polycythemia/hyperviscosity syndrome. Increased red cell mass is directly correlated with hyperviscosity. Hyperviscosity or red cell sludging can have severe consequences since it can damage any organ. Seizures and gastrointestinal injury are among the major complications of hyperviscosity. Several mechanisms have been proposed but not proven for polycythemia in IDMs. These include increased hematopoiesis, possibly as a consequence of intrauterine hypoxia or enhanced placental transfusion at delivery. The primary therapy for the polycythemia/hyperviscosity syndrome is partial exchange transfusion to reduce red cell mass.

Hyperbilirubinemia

Neonatal hyperbilirubinemia occurs more frequently in IDMs because of increased red cell breakdown.⁵¹ Some of this may be due to increased red cell mass, and diminished red cell distensibility, with a consequent increase in the generation of bilirubin for hepatic conjugation and excretion. The delay in the switch in production from Hgb F to Hgb A may also be a factor. It is also possible that as a consequence of altered maternal metabolic fuel availability, red cell membrane composition in IDMs may differ from normal, resulting in increased susceptibility and hemolysis. In addition, the macrosomia of the IDM can increase the risk of bruising at delivery and thereby also augment bilirubin production.

Hypertrophic Cardiomyopathy

Many IDM neonates have a thickened interventricular septum and left or right ventricular wall.⁵² While most such infants are asymptomatic, some develop congestive heart failure as a result of left ventricular outflow obstruction.⁵³ These abnormalities generally regress over 3–6 months. Since cardiac muscle is responsive to insulin, it has been suggested that the cardiomyopathy represents an acquired defect linked to the increased availability of insulin during fetal life. This possibility is strengthened by the fact that hypertrophic cardiomyopathy has been reported in infants of women with gestational diabetes.⁵⁴

“Lazy Left Colon”

A functional bowel anomaly unique to IDMs may present as neonatal gastrointestinal obstruction. Barium contrast studies are suggestive of aganglionic megacolon. However, unlike Hirschsprung's disease, bowel innervation is normal in this “lazy left colon” or “small left colon” syndrome so that normal bowel function eventually supervenes.⁵⁵

LONG-RANGE IMPLICATIONS OF THE INTRAUTERINE ENVIRONMENT: FUEL-MEDIATED TERATOGENESIS

Some of the above diabetes-related changes affect cells which may be terminally differentiated at birth and thought to undergo relatively limited replication thereafter (e.g., adipocytes, β cells of the pancreas, brain cells, etc.). These relationships prompted Freinkel to suggest that the actions of maternal fuels in developmental biology should be viewed in pharmacological as well as nutritional dimensions.^{8,56,57} He proposed that abnormal fuel delivery *in utero* could exert permanent long-range effects upon the offspring (“fuel-mediated teratogenesis”^{8,57}). For example, maternal hyperglycemia, hyperaminoacidemia, or elevated free fatty acids during the second half of pregnancy when fetal adipocytes, muscle cells, pancreatic cells, and neuroendocrine networks are undergoing proliferation and differentiation might confer greater vulnerability for obesity or type 2 diabetes mellitus (T2DM) in later life; abnormal fuel mixtures during the first and second trimester when the brain is established and brain cells are being formed might result in subsequent neurologic, psychologic, or cognitive deficits; and disturbances in the early part of the first trimester during embryogenesis might compromise organogenesis and so produce birth defects (fuel-mediated organ teratogenesis).^{8,57}

In recent years, many reports have been published in support of the concept of fuel-mediated teratogenesis. A substantial proportion of the data have come from the long-term follow-up of offspring of diabetic mothers at the Northwestern University Diabetes in Pregnancy Center and the National Institutes of Health Pima Indian studies. These results and others will be summarized in the sections that follow.

Birth Defects

Although the development birth defects in pregnancies complicated by diabetes mellitus provides compelling confirmation of Freinkel's original hypothesis, this topic will not be considered in detail here. As indicated above and in Chap. 38, a metabolic basis for diabetic embryopathy has been established, although neither the precise time nor duration of exposure to an abnormal metabolic environment necessary for adverse events to develop in the human embryo has been pinpointed. It has also been demonstrated that the risk of diabetic embryopathy can be eliminated by good metabolic control around the time of conception. However, because participation in programs that provide such preconception care is far from universal, this form of fuel-mediated teratogenesis continues to be seen with alarming frequency.

Behavioral and Intellectual Functions

The possibility of long-term neurologic deficits in the offspring of diabetic mothers has been recognized for a number of years.³ Yssing encountered "cerebral handicaps of definite clinical significance" in 18% of neonatally surviving Danish children born between 1946 and 1966 with a birthweight greater than 1000 g.⁵⁸ Obvious factors, such as prolonged severe neonatal hypoglycemia, birth trauma, neonatal kernicterus, and others have been implicated in many such cases in the past.⁵⁹⁻⁶¹ However, more subtle adverse effects have also been ascribed to fuel metabolism-related pathology. An apparent correlation between acetonuria during pregnancy and diminished IQ in the offspring prompted the suggestion that ketonemia may impair long-term intellectual performance.^{62,63} The deleterious effects were attributed to ketones *per se* since they were encountered following all types of acetonuria (i.e., that caused by diabetes as well as malnutrition). These retrospective epidemiologic observations have been challenged,⁶⁴ although the demonstration by Shambaugh that ketones can inhibit pyrimidine⁶⁵ and purine⁶⁶ metabolism in fetal rat brain cells could provide some biochemical basis.

The longitudinal observations of the Northwestern University Diabetes in Pregnancy Center have included detailed analysis of neuropsychological development in offspring of diabetic mothers. On average, these offspring experienced minimally abnormal intrauterine fuel exposures. Significant mental deficiency was no different than national estimates in this group of offspring of mothers with well-controlled gestational and pregestational diabetes. Direct correlations were found between poorer maternal glucoregulation during the second and third trimester and poorer performance at birth in the interactive, motor, and physiologic dimensions of the Brazelton Neonatal Behavioral Assessment Scales.^{67,68} Similarly, direct correlations between mild maternal ketonemia in the second and third trimester and poorer performance on both the Mental Development Index of the Bayley Scales of Infant Development at age 2 and the Stanford-Binet Intelligence Scales at ages 3-5 years have been reported.⁶⁹ Finally, average scores on the WISC-R Full Scale IQ at ages 7-11 years were inversely correlated with mater-

nal HbA_{1c} in the second trimester and β -OHB in the third trimester. Impaired psychomotor development at 6-9 years of age, as assessed by the Bruininks-Oseretsky Test of Motor Proficiency, is also associated with maternal ketonemia in the second and third trimesters.⁷⁰ In these studies, careful perinatal and neonatal care were provided and perinatal morbidities were generally of mild or moderate severity. The perinatal morbidities associated with being an IDM did not appear to be responsible for adverse psychomotor and cognitive outcomes. Analysis of child educational achievement⁷¹ demonstrated lower scores on the arithmetic index that correlated with higher maternal third-trimester free fatty acids, but no other correlations were observed. The above correlations between intrauterine metabolism and development in childhood persist when controlled for socioeconomic status and ethnicity. Moreover, they are not substantially different in gestational than in pregestational diabetes mellitus. Behavioral adjustment scales did not significantly correlate with indices of antepartum maternal metabolism. However, correlations were observed between obesity in the offspring and internalizing behavior problems.⁷²

Data reported from Denmark are also consistent with the postulate of congenital fuel-mediated behavioral effects.⁷³ Denver Developmental Tests in the offspring of diabetic mothers at age 4 were correlated with their prior patterns of early intrauterine growth as measured by ultrasound during weeks 7-14 of pregnancy. Researchers encountered abnormal tests in 32.3% of the 34 4-year-olds who had displayed "early growth delay" (presumably reflective of faulty intrauterine milieu, since such delayed growth occurs in the offspring of mothers with the most elevated values for glycosylated hemoglobin at that time).⁷⁴ By contrast, Denver Developmental Tests were abnormal in only 8.0% of the 50 offspring from diabetic mothers whose intrauterine rates of growth had been normal during weeks 7-14 of pregnancy and in 11.6% of 86 4-year-olds from nondiabetic mothers.⁷⁵

Sells and colleagues compared neurodevelopment through 36 months of age in 109 infants of mothers with T1DM and 90 control infants.⁷⁵ Mothers who were enrolled in a program of strict glycemic control before or within 21 days of conception had lower glycosylated hemoglobins than mothers enrolled later. Neurodevelopment of the offspring of earlier-enrolled mothers was similar to the control infants, whereas offspring of the later-enrolled mothers scored less well on tests of language development. There were no differences on the Bayley Scales of Infant Development or the Stanford-Binet Intelligence Scale.

Such experiences have not been universal—Several retrospective surveys have failed to disclose an increased incidence of gross neurologic and/or IQ deficits in the offspring of diabetic mothers.^{76,77} However, negative reports need not necessarily exclude the possibility of small correlations between perturbations of maternal metabolism at key stages in pregnancy and long-range behavioral and/or intellectual performance.

Obesity

A number of analyses of the offspring of diabetic parents have disclosed disparities in weight relative to height during childhood and adolescence.^{60,78-82} Vohr and coworkers observed that this obesity tends to correlate with birthweight.^{82,83} However, this association was not found by others.⁶⁰ White⁸⁰ and more recent workers^{84,85} noted that the obesity is far more frequent in the offspring of diabetic mothers than diabetic fathers. However, none of the early reports provided direct correlations with metabolic status during intrauterine development.

In the Northwestern University Diabetes in Pregnancy Center study, neonatal macrosomia in offspring of diabetic mothers disappeared by 1 year of age.⁸⁶ This contrasts with data from the general population, where large neonates tend to remain larger than average for at least the first 5 years of life.⁸⁷ After 2–3 years of age, offspring of diabetic mothers tend to gain weight faster than other children, and rapid weight gain is observed after 5 years of age.²² By 8 years of age almost half of the offspring of diabetic mothers in this cohort had a weight greater than the 90th percentile.⁸⁸ This trend continues into adolescence, with rather dramatic increases in body mass index for the highest quartile (Fig. 39-3). Significant differences were not observed between offspring of mothers with gestational diabetes mellitus (GDM) when compared to offspring of mothers with pregestational diabetes mellitus (PGDM). Additionally, these studies have provided evidence that fetal islet function may confer predictive insights concerning long-term anthropometrics. Relative obesity in childhood, at ages 6–8 years, is significantly correlated with insulin secretion *in utero* (as judged by amniotic fluid insulin content at week 32–34 of pregnancy),⁸⁹ as is relative obesity in adolescence, ages 14–17 years.⁸⁶

In a study of 71 offspring of mothers with T1DM, Weiss and associates found correlations between amniotic fluid insulin measured at 31 ± 2 weeks gestation and body mass index at 5–15 years of age.⁹⁰

Further compelling support for an effect of antepartum maternal glucoregulation on the subsequent anthropometric development of the offspring has come from the Pima Indian Study, an NIH-supported epidemiologic survey initiated in 1965 to secure longitudinal characterizations of diabetes in a relatively pure genetic group having “the highest reported incidence and prevalence of type 2 diabetes.”⁹¹ The subjects consist of Pima Indians (and some Papago Indians) who live in the Gila River Indian community of Arizona. As part of that study, each community resident over 5 years of age is asked to have an examination which includes

measurements of height and weight and a modified glucose tolerance test approximately every 2 years.

Pettitt and coworkers have correlated the two-hour response of Pima Indian mothers to oral glucose during pregnancy with the occurrence of obesity in their offspring.⁸⁵ They have found that obesity ($\geq 140\%$ of standard weight for height) is present at age 15–19 in two-thirds of the offspring who were presumably exposed to an abnormal intrauterine environment by virtue of their mothers being diabetic during gestation. By contrast, they have encountered obesity in only 40% of the 15- to 19-year-olds whose mothers had the genetic propensity for obesity and diabetes, but did not become diabetic until after the pregnancy (i.e., “prediabetic mothers”) and in 30% of the offspring whose mothers never became diabetic (i.e., “nondiabetic mothers”).⁸⁵ Moreover, offspring of diabetic women were heavier than offspring of nondiabetic and prediabetic women regardless of birthweight.⁹² Thus although the characterizations of the Pima Indian pregnancies on the basis of a single 2-hour post-glucose load preclude correlations with fuels other than glucose, or with metabolic status throughout pregnancy, the overall experiences are consistent with the theory of fuel-mediated “anthropometric” teratogenesis.^{8,57} The report from Italy of greater relative weight-to-height at age 4 in the offspring of diabetic mothers whose control was “poor” rather than “good” during the index pregnancy⁹³ provides additional support. However, well-controlled, mild gestational diabetes may not increase risk of obesity in offspring before the age of 10 years.⁹⁴ Others continue to report an increase in obesity in offspring of women with T1DM.⁹⁵ In a study of 200 offspring of diabetic mothers, Plagemann and colleagues found obesity in offspring of mothers with both gestational and T1DM at 1–4 and 5–9 years of age.⁹⁶

Abnormal Glucoregulation and Diabetes Mellitus

Diabetes has been classically viewed as a genetic disorder, and “diabetic genes” have been invoked to explain the increased incidence of diabetes in the offspring of diabetic parents. Attempts to assess whether the “inheritance” may be influenced by congenital factors have been complicated by the failure of early reports to differentiate between parental type 1 and type 2 diabetes (which may differ in patterns of inheritance; see below), and the failure to distinguish between maternal diabetes occurring during the index pregnancy or thereafter (since such temporal factors may have different developmental implications for the conceptus; see above).

Evidence from animal models and epidemiologic studies suggests that disturbance in islet function or development during intrauterine and early postnatal life, produced by a variety of mechanisms, predisposes to metabolic disturbances and impaired glucose tolerance in later life. Thus offspring of rats with streptozocin-induced diabetes during pregnancy develop impaired glucose tolerance and gestational diabetes mellitus.⁹⁷ When pregnant rats are made mildly hyperglycemic by glucose infusion in late gestation, the offspring develop impaired glucose tolerance.⁹⁸ In crosses between rats with spontaneous T2DM and nondiabetic rats, a greater degree of glucose intolerance was observed in the offspring if the mother was diabetic, rather than the father.⁹⁹ Rhesus monkeys made hyperinsulinemic, but euglycemic, *in utero* by infusion of insulin into the fetus develop abnormal glucose tolerance as pregnant adults.¹⁰⁰ In studies of rats, adult offspring of diabetic mothers showed hyperphagia, basal hyperinsulinemia, and impaired glucose tolerance, and were overweight. This was accompa-

FIGURE 39-3. Physical growth of offspring of diabetic mothers expressed as body mass index (BMI). Solid lines indicate percentiles for BMI of normal American children as published by NCHS¹³⁰; dashed lines depict 25th, 50th, and 75th percentiles for ODM. Data were smoothed by fitting to a third order regression.¹¹⁵

nied by an elevated number of neuropeptide Y neurons and galanin neurons in the arcuate hypothalamic nucleus.¹⁰¹ Plagemann and colleagues also report disturbed differentiation and organization of distinct hypothalamic nuclei and subnuclei in hyperinsulinemic offspring of diabetic rats, possibly leading to dysfunctions of hypothalamic regulators of body weight and metabolism.¹⁰²

Inferential insights concerning intrauterine fuel exposures and later susceptibilities to diabetogenic challenges can be made by analyzing the family histories of gravida with GDM.¹⁰³ T2DM should be present with equal frequency in the mothers and fathers of patients with GDM if sensitivity to the diabetogenic stresses of pregnancy were determined wholly by genetic factors (especially since meaningful sex differences in the incidence of T2DM have not been reported). On the other hand, if some limitations of functional reserve were “acquired”¹⁰⁴ in the course of prior intrauterine experiences,^{104–109} a higher incidence of diabetes in the mothers than in the fathers of patients with GDM might be anticipated. A survey disclosed a history of maternal diabetes in 33% of gravidas with GDM, in contrast to a history of maternal diabetes in only 4.8% of normal gravidas.¹⁰³ On the other hand, the history of T2DM in the fathers of the two groups of gravidas was not different—8.8% in the women with GDM and 6.0% in the women with normal carbohydrate metabolism.¹⁰³ Hence, as first described in animal experiments by Bartelheimer and Kloos,¹⁰⁵ and supported by the pioneering clinical observations of Hoet¹⁰⁶ and Dörner and colleagues,^{107,108} some transgenerational vulnerability to diabetogenic challenges may indeed occur as a consequence of prior intrauterine fuel exposures.

Mutations in mitochondrial DNA occur in association with a maternally-inherited form of diabetes and nerve deafness.^{110,111} In Japanese subjects with T2DM and a family history of diabetes, a mutation in mitochondrial DNA was found in 60% of those with deafness, but only 2% of individuals with unimpaired hearing.¹¹² A mutation in mitochondrial DNA was found in only one of 218 unrelated British subjects with T2DM.¹¹³ Since mitochondria are maternally inherited, these mutations may contribute in a rather limited way to the observed excess of maternal diabetes in subjects with T2DM.

Studies in Hattersley’s laboratory have determined that up to 6% of gestational diabetes in the United Kingdom is the result of a mutation in the maternal glucokinase gene. In offspring of these mothers, the fetal genotype influences birthweight and glucose at birth. In the presence of a fetal glucokinase mutation, birthweight was reduced by a mean of 640 grams, and glucose was higher by a mean of 1.2 mmol/L.¹¹⁴

The offspring of gravidas enrolled in the Northwestern University Diabetes in Pregnancy Center long-term follow-up are demonstrating an increased frequency of impaired glucose tolerance. Plasma glucose and insulin have been measured fasting and 2 hours after oral glucose administration (1.75 g/kg) yearly beginning at 1.5 years of age. At 14–17 years of age, mean fasting glucose concentration in the ODM is no different than in 80 control subjects, and fasting insulin concentrations are identical. However, 2-hour concentrations after a glucose load are 6.5 ± 1.3 mmol/L and 5.7 ± 0.9 mmol/L ($p < 0.001$) respectively, and 2-hour post-glucose load insulin concentrations are 449 (90% CI: 177–1140) pmol/L in the ODM, compared to 331 (90% CI: 140–699) pmol/L in control subjects ($p < 0.01$). Two subjects have developed T2DM that was first detected on yearly glucose tolerance testing. One subject developed T1DM with ketoacidosis. In addition, 28 subjects have had impaired glucose tolerance (2-hour glucose

concentration greater than 7.8 mmol/L) on at least one occasion between 8 and 17 years of age. This is displayed as a cumulative probability (Kaplan-Meier estimator) in Fig. 39-4. On a single test 2 of 80 control subjects had a 2-hour glucose concentration greater than 7.8 mmol/L. The relative risk of impaired glucose tolerance (2-hour post-glucose load glucose concentration >7.8 mmol/L) 4.7 (95% CI: 1.7–12.9) for offspring who had an elevated mean amniotic fluid insulin concentration.¹¹⁵ Plagemann and colleagues also report an increased incidence of impaired glucose tolerance in offspring of mothers with both gestational diabetes and T1DM. Furthermore, they found correlations between insulin:glucose ratios in childhood, and those previously obtained at birth.¹¹⁶

In general, populations with a high prevalence of impaired glucose tolerance later become populations with high prevalences of T2DM.¹¹⁷

The Pima Indian studies provide additional evidence. Pettitt and associates reported that T2DM is present by age 20–24 in 45.5% of the offspring of “diabetic mothers,” but in only 8.6% and 1.4% of the offspring of “prediabetic” or “nondiabetic mothers,” respectively (see above for definition of these categories).¹¹⁸ Moreover, these differences persisted even after taking into account diabetes in the father, age at onset of diabetes in either parent, obesity in the offspring. In a study of Pima siblings born before or after the mother’s development of diabetes, those exposed to maternal diabetes *in utero* had a 3.7-fold greater risk of developing diabetes.¹¹⁹ Pettitt and coworkers conclude that “the intrauterine environment is an important determinant of the development of diabetes and that its effect is in addition to effects of genetic factors.”¹¹⁸ In another study, Pettitt and colleagues found a lower rate of T2DM in Pima offspring who were exclusively breastfed for the first 2 months of life;¹²⁰ however, this report was not specific for offspring of diabetic mothers.

Some of the female offspring of the Pima women in the above studies have been examined during their pregnancies. A significant

FIGURE 39-4. Cumulative probability (Kaplan-Meier estimator) of impaired glucose tolerance (IGT) or diabetes in offspring of diabetic mothers.¹¹⁵

correlation (partial correlation 0.304, $p = 0.011$) was found between 2-hour post-glucose load plasma glucose in 15- to 24-year-old Pima women and their mothers' 2-hour glucose value during pregnancy, after controlling for age.¹²¹ Thus, subsequent generations may be at even greater risk for the development of diabetes than would be predicted on a genetic basis alone.

Converse congenital relationships may also pertain in T1DM. Retrospective studies by Warram and coworkers,¹²² in their reanalysis of some of the published reports of others,^{123,124} have disclosed a two- to fivefold greater risk for the development of T1DM in the offspring of fathers than mothers with T1DM. These researchers have suggested that the seeming maternal protection against subsequent T1DM may be due to an induction of immunologic tolerance to the autoantigens of the β cells during intrauterine development.¹²⁵ Weiss and coworkers examined offspring of diabetic mothers at 5–15 years of age. Upon oral glucose tolerance testing, they find higher glucose, insulin, and C peptide concentrations, especially in those offspring who had higher amniotic fluid insulin concentrations *in utero* at 31 ± 2 weeks.⁹⁰ Thus although the directional impacts may be different, current data indicate that nature (as embodied by genetic propensities) may be modified by nurture (as determined by congenital contributions via the intrauterine metabolic environment) in the pathogenesis of T1DM as well as T2DM.

Other Cardiovascular Risk Factors

In the Northwestern Diabetes in Pregnancy Center Study, body mass index, blood pressure, and lipid concentrations were examined in ninety nine offspring of diabetic mothers and 80 controls. ODM were more obese (BMI 22.5 ± 5.6 vs. 20.3 ± 4.0 kg/m²), and had higher systolic (8 mm Hg) and mean arterial BP (4 mm Hg), but similar diastolic BP compared to controls. ODM had lower fasting concentrations of LDL (2.54 ± 0.67 vs. 2.82 ± 0.70 mmol/L) and total cholesterol (4.01 ± 0.80 vs. 4.40 ± 0.78 mmol/L). In both groups, BMI, triglycerides, and fasting and 2-hour glucose concentrations showed correlations with BP measurements. Fasting insulin correlated with BP readings only in the ODM. Correlations were found between second- and third-trimester maternal free fatty acid concentrations and diastolic and mean arterial BP. Third trimester β -hydroxybutyrate was correlated with mean arterial BP.¹²⁶ The increased prevalence of obesity, impaired glucose, and elevated blood pressure may predispose offspring of diabetic mothers to an increased risk of heart disease in adulthood.

As noted above, obesity and impaired glucose tolerance, but not lipid metabolism, are associated with elevated amniotic fluid insulin measured in the third trimester. Thus the cause of physiologic predisposition towards elevated blood pressure may differ from those factors which contribute to elevations in body weight and reduced glucose tolerance.

General Relevance for Development in Later Life

The proposition that maternal fuel metabolism may exert long-range effects on development (i.e., the hypothesis of "fuel-mediated teratogenesis,"^{8,57}) is being corroborated by many retrospective and prospective experiences. As such, there are now more reasons than ever to normalize maternal metabolism in all pregnancies complicated by diabetes and for viewing the success of preg-

nancy outcome in terms of the entire lifetime of the progeny as well as traditional perinatal criteria. Appropriate management of the pregnant diabetic may thereby constitute a meaningful strategy for modifying some of the self-perpetuating, and apparently congenitally-acquired contributions to such public health problems as adult obesity and diabetes mellitus.

Moreover, these fuel-related phenomena need not be limited to pregnancies complicated by diabetes. The same relationships between ambient fuels, fetal insulin secretion, and gene expression *in utero* may well apply to all pregnancies, so the potential for fuel-mediated teratogenesis may be present whenever maternal metabolism is perturbed for any reason.^{57,127} Hales and colleagues have found that impaired growth *in utero* and in infancy is associated with impaired glucose tolerance and T2DM in adulthood.¹²⁸ McCance and associates, studying the Pima Indian population in Arizona, where most large babies are offspring of diabetic mothers, report a U-shaped relationship between birthweight and the later development of both obesity and diabetes in the offspring, with both extremes of neonatal size inducing abnormalities to a greater degree than those of more normal (average) birthweight.¹²⁹ However, in the general population, large babies of normal mothers have a low risk of obesity and diabetes. Thus diabetes in pregnancy has merely served as a paradigm for a more general truism,¹²⁷ and the broad ramifications for all of fetomaternal medicine extend far beyond the more parochial preoccupation with diabetes *per se*. To quote Freinkel and Metzger, "No single period in human development provides a greater potential (than pregnancy) for long-range 'pay-off' via a relatively short-range period of enlightened metabolic manipulation."⁵

Acknowledgments The authors are grateful to their many collaborators in the Departments of Medicine, Obstetrics, and Pediatrics who have contributed to The Northwestern University Diabetes in Pregnancy Center studies that are cited in this chapter.
